ABSTRACT

The relationship between residual stresses and microstructure associated with a laser powder bed fusion (LPBF) IN718 alloy has been investigated on specimens produced with three different scanning strategies (unidirectional Y-scan, 90° XY-scan, and 67° Rot-scan). Synchrotron X-ray energy-dispersive diffraction (EDXRD) combined with optical profilometry was used to study residual stress (RS) distribution and distortion upon removal of the specimens from the baseplate. The microstructural characterization of both the bulk and the near-surface regions was conducted using scanning electron microscopy (SEM) and electron backscatter diffraction (EBSD). On the top surfaces of the specimens, the highest RS values are observed in the Y-scan specimen and the lowest in the Rot-scan specimen, while the tendency is inverted on the side lateral surfaces. A considerable amount of RS remains in the specimens after their removal from the baseplate, especially in the Y- and Z-direction (short specimen dimension and building direction (BD), respectively). The distortion measured on the top surface following baseplate thinning and subsequent removal is mainly attributed to the amount of RS released in the build direction. Importantly, it is observed that the additive manufacturing microstructures challenge the use of classic theoretical models for the calculation of diffraction elastic constants (DEC) required for diffraction-based RS analysis. It is found that when the Reuß model is used for the calculation of RS for different crystal planes, as opposed to the conventionally used Kröner model, the results exhibit lower scatter. This is discussed in context of experimental measurements of DEC available in the literature for conventional and additively manufactured Ni-base alloys.

Introduction

Inconel 718 (IN718) is a Ni-based superalloy with widespread application at high temperatures (up to 650 °C) and corrosive environments such as those encountered in gas turbines, due to an excellent combination of strength, resistance to oxidation and corrosion, favourable weldability, as well as good fatigue and creep properties [1]. Nevertheless, the low thermal conductivity and high hardness of IN718 pose limitations to the use of conventional forming processes. The use of additive manufacturing (AM) techniques can greatly resolve these limitations [2, 3], offering the advantages of increasing design complexity and cost saving via the optimization of material usage.

The AM process parameters highly influence the resulting microstructure, the level of residual stress (RS) and the defect content. In particular, the scanning strategies have a remarkable effect on the solidification texture as they control the directionality of the heat flux [4]. Also, the cooling rates at the melt pool can lead to columnar, mixed, or equiaxed grain growth depending on the scanning strategy used [5]. The columnar grains are usually formed with the longest axis parallel to the building direction (BD). Note that the cooling rates induced in the bulk are not usually the same at the free surfaces, which tend to develop equiaxed grains regardless of the technique, material, and process parameter utilized [6–8].

Laser powder bed fusion (LPBF) is an AM technique whereby a thin layer of metallic powder under an inert gas atmosphere is selectively melted via a high energy laser beam. This technique is known to introduce high magnitudes of internal stresses that, when uncontrolled, may lead to specimen cracking, RS, and distortion [9–11]. RS are inhomogeneous self-equilibrating stresses (and moments) present in a body in the absence of external forces, temperature gradients, or moments. They appear whenever a material experiences a heterogeneous inelastic strain such as when the material is plastically deformed in a non-uniformly manner [12]. The residual stresses are often defined by the length scale over which they balance. The long-range macro-stress (termed Type I) equilibrates over the whole body (e.g. over a component). The shorter-range micro-stresses, intergranular (Type II) and intragranular (Type III) balance

over many grains or over a single grain or part of a grain, respectively. The current study focuses on the long-range macro-stresses (i.e., Type I).

The principal mechanisms controlling the residual stress build-up during LPBF have been described to be twofold [3, 13]: (i) the temperature gradient mechanism (TGM), which refers to the induced stresses and strain occurring locally in the laser-beam irradiated area; and (ii) the cool-down phase mechanism, which accounts for the shrinkage mismatch between the previously melted material and the solidifying layer. In the general case, the resulting RS fields tend to be tensile at the surface and compressive in the bulk. This trend has also been observed in LPBF IN718 alloys, where tensile RS close to the yield strength has been observed at the surface regions, while the bulk exhibits compressive RS magnitudes of lower magnitudes than the tensile ones [14–16].

One of the widely adopted RS mitigation strategies consists of adapting the scanning strategies in order to homogenize and reduce thermal stresses during the process [17–19]. For example, unidirectional scanning strategies localize the heat over the same path upon deposition of successive layers. Moreover, using a scanning vector parallel to the longest dimension of a specimen leads to steeper thermal gradients. On the other hand, an interlayer alternation in the direction of the scan-vector reduces the heat concentration at a particular location. In this regard, a 67° interlayer avoids the repetition of the scan-vector direction for a maximum number of layers and it has been reported to reduce distortion, anisotropy, and surface roughness [20].

In LPBF, the surface roughness principally varies depending on the process parameters and on the orientation of the build direction with respect to the recoating blade [21–23]. The surface roughness severity is a limiting factor when measuring surface and near-surface RS since it locally relaxes the stress, creating gradient of increasing stress towards the interior [24, 25]. Thus, the influence of the process parameters (in our case the scanning strategy) on the surface roughness needs to be considered when measuring surface/near-surface RS.

In spite of the considerable amount of work reported so far on the characterization of AM IN718 alloys, there are still some remaining uncertainties due to the limited reproducibility, predictability, and microstructural complexity of the resulting products. These uncertainties have a considerable influence on

the interpretation of results, sometimes invalidating comparisons among available literature sources. Moreover, the coarse-grained and strongly textured microstructures, which can be characteristic of certain AM processes or scanning strategies, pose a challenge to data analysis when using diffraction-based techniques. For instance, the chosen diffraction elastic constants (DEC, used for the connection between the diffraction measured micro-strain and the macro-stress) can lead to significant variations of the calculated residual stress [26]. The correct determination of the magnitude of residual stresses is expected to be crucial for the understanding of the mechanical performance of components. In this regard, the DEC measured in a LPBF Ti-6Al-4V alloy have been already reported to deviate from the DEC values of conventionally produced Ti-6Al-4V [27]. Note that the need to assess the validity of conventional DEC is not exclusive to AM materials, since this requirement is valid for any new material exhibiting unconventional microstructures.

The classic theoretical models of Voigt, Reuß, and Kröner continue to be used to calculate the DEC for the RS analysis from diffraction data. The Voigt model represents a limiting case whereby each different grain has the same strain [28]. It is generally to be avoided for the calculation of RS in materials with high anisotropy since it does not take elastic anisotropy of the various hkl reflections into account. The Reuß model represents another limiting case and assumes that the stress is constant between grains [29]. Crystallites in a polycrystalline aggregate develop strains proportional to the anisotropic modulus for their particular orientation. The Kröner model allows both stresses and strains to vary between grains that have arbitrary orientations. It takes advantage of the Eshelby inclusion model to calculate the overall stiffness of a grain embedded in a continuum matrix, which is exposed to a specific homogeneous stress field [30, 31]. Introduction to these models can be found in textbooks such as [26, 32]. Many efforts have been and continue to be dedicated to the improvement of the fundamental models [33–35]. Such improvements have been directed to include the effect of texture.

With this view, we consider that two fundamental points are so far missing in the AM literature: (i) the textured microstructures resulting from AM necessitates a redefinition of the diffraction elastic constants (DEC) used for the calculation of macro-stresses; and

(ii) the formation of RS and microstructure are so far addressed in the literature as two independent results from the selection of the scanning strategy: we propose that in fact they are interconnected, and that this relationship needs to be studied in further detail. In this regard, a previous work by the authors has shown that highly textured columnar grains (i.e., anisotropic grain structure), as opposed to mildly textured elongated grains, can more easily accumulate strain dislocations along the building direction, which is considered to lead to increased RS relaxation [25].

The present work compares the near-surface RS state and degree of distortion upon removal from the baseplate of a LPBF IN718 material produced using different scanning strategies. The studied interlayer scanning strategies are Y-unidirectional (corresponding to the shortest XY-plane direction), XY-alternation, and 67°-rotation. The investigation was conducted by combining laboratory X-ray diffraction (LXRD), synchrotron X-ray energy-dispersive diffraction (EDXRD), and optical profilometry techniques. Detailed characterization of the microstructure via scanning electron microscope (SEM), energy-dispersive spectroscopy (EDS), and electron backscatter diffraction (EBSD) allowed further interpretation of the EDXRD results. The pertinence of using the Reuß model instead of the Kröner model for AM materials is evaluated. Finally, the differences in microstructure and RS states as a function of the scanning strategy are discussed.

Materials and experimental methods

Materials and processing

The specimens were supplied by Siemens AG, Power and Gas Division, Berlin, Germany. The manufacturing was performed using an EOS M290 machine in an argon atmosphere with low level of oxygen to avoid oxidation. An IN718 pre-allowed powder was used entirely in a virgin (not recycled) condition and the powder layer thickness was 40 μm . Figure 1a–c shows the three scanning strategies investigated in the present work. Note that the three studied specimens were produced in the same build job, have the same orientation with respect to the recoater and the inert gas flow, and are aligned at different positions along the Y-axis. The hatching stripe (HS) width

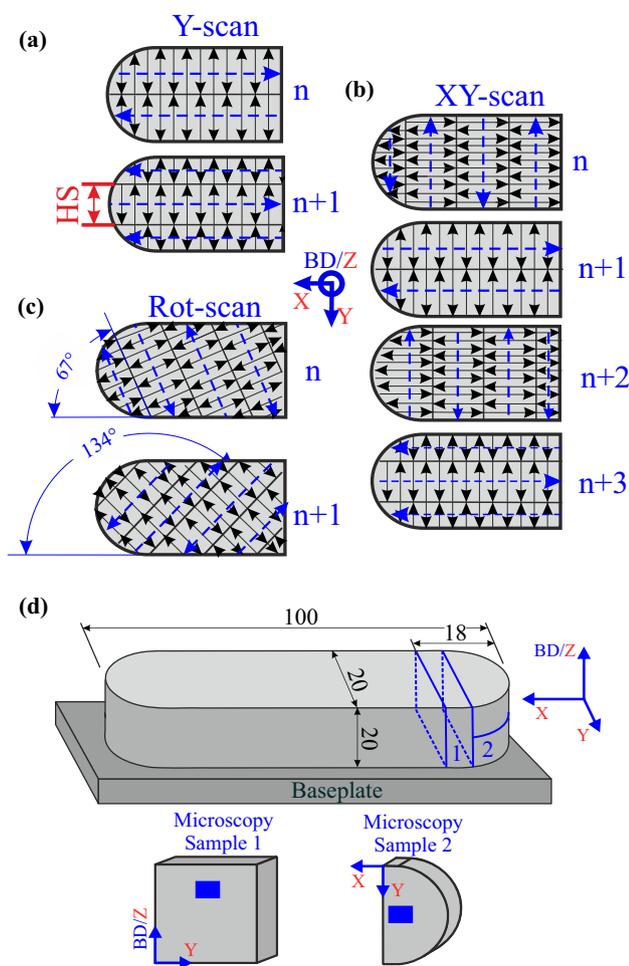

Figure 1 Schematic illustration of the studied scanning strategies corresponding to **a** the Y-scan specimen, **b** the XY-scan specimen, and **c** the Rot-scan specimen. The black arrows indicate the rastering directions and the blue arrows the direction of advancement of the rastering within each strip. **d** Illustration showing the specimen geometry (units in millimetres) and the location where the microscopy samples were extracted (top). corresponds to 1/10 of the length of the specimens (in the X-direction). The specimen dimensions are $100 \times 20 \times 20 \text{ mm}^3$ (see Fig. 1d). The building direction (BD) corresponds to the Z axis. The top surface of all the specimens was subjected to an up-skin process (corresponding to the last three layers, $\sim 120 \mu\text{m}$), where the volumetric energy density was 4% lower than that applied to the rest of the specimen. The remaining process parameters are proprietary to Siemens AG and cannot be disclosed. The nominal yield strength in the as-fabricated condition

is $\sigma_{y//BD} = 632 \text{ MPa}$ (parallel to the Z/BD-direction) and $\sigma_{y\perp BD} = 806 \text{ MPa}$ (perpendicular to the build direction). These values are similar to those reported in the literature [36, 37].

Microscopy

Microstructural characterization of the specimens was performed using a LEO 1530VP (ZEISS) scanning electron microscope (SEM) equipped with an electron backscatter diffraction (EBSD) Bruker Nano e-Flash HD 5030 detector, as well as an energy-dispersive spectroscopy detector (EDS, XFlash 5030). The SEM was operated at an acceleration voltage and beam current of 20 kV and $\approx 7 \text{ nA}$, respectively. The ESPRIT 1.94 package from Bruker Nano was used for data collection and pattern indexing. Post-processing was performed using MTEX software [38]. The microscopy samples (see Fig. 1d) were prepared using standard metallographic grinding and polishing. The final polishing was achieved using $0.02 \mu\text{m}$ colloidal silica suspension.

Note that the microscopy samples were extracted from one end of the specimen. This extraction was conducted while the specimens were still attached to the 36 mm thick baseplate. It has been shown that this sectioning has a negligible effect on the RS state of the other end of the specimen [39].

Laboratory X-ray diffraction (LXRD)

The specimens were examined in three conditions: (i) the As-Built condition, corresponding to the state with the original baseplate thickness (36 mm), (ii) the Thin-Baseplate condition, corresponding to the state after baseplate thinning to 6 mm thickness, and (iii) the Released condition, corresponding to the state where the baseplate was completely removed from the specimen. Both the thinning of the baseplate and the removal of the specimens from baseplate were performed using electro-discharge machining (EDM). Note that the use of the LXRD technique was confined to study the effect of the baseplate thinning on the top surfaces along a central line parallel to the X-direction.

The surface RS analysis was performed using a Xstress G3 diffractometer (StressTech, Vaajakoski, Finland). This instrument works in angular dispersive (AD) X-ray diffraction mode and is equipped with a movable arm carrying an X-ray source and

two position-sensitive detectors that revolve around a stationary specimen. A MnK_{α} radiation source was used with a collimator aperture of 2 mm in diameter. The exposure time for each recording was 5 s. The penetration depth of the X-ray laboratory source in Ni is estimated to be $\sim 5 \mu m$. The Ni-311 reflection ($2\theta = 156^\circ$) was measured in an angular tilt range from $\psi = -45^\circ$ to $\psi = 45^\circ$ with a total of 19 steps. The acquired data were processed with the software Xtronic and the Pearson VII function was used for the peak fitting. The RS was calculated using the $\sin^2 \psi$ -method with the elastic constants for Ni-311 reflection calculated by the Reuß model (Young's modulus of 178 GPa and Poisson's ratio of 0.34).

Synchrotron X-ray energy-dispersive diffraction (EDXRD)

Near-surface RS analysis was performed at the EDDI beamline [40], at the synchrotron facility BESSY II (Helmholtz Zentrum Berlin (HZB), Germany). This beamline operated in energy-dispersive mode and provided a white beam with an energy range of about 10 keV–150 keV. Apart from the increased penetration power due to the higher X-ray energies available, the advantage of energy-dispersive (ED) diffraction compared to angle dispersive (AD) is the data acquisition. Only single line profiles are usually measured in the AD mode for set-ups with fixed positions of both specimen and detector. On the other hand, the ED mode of diffraction gives complete diffraction spectra with a multitude of reflections for the equivalent set-up (i.e., fixed scattering vector). The fact that each reflection corresponds to different X-ray energies leads to the measurement of a depth-resolved residual stress profile.

The RS state (corresponding to Type I stresses) was investigated by mapping the equivalent regions on the top surfaces and one of the lateral surfaces (termed Surface 1) of all the specimens (see Fig. 2a). The reflection-mode measurements were taken with the specimens mounted on an Euler cradle. Since this cradle could not carry more than 5 kg, only the Thin-Baseplate and Released conditions were investigated with EDXRD (Fig. 2b). The diffraction angle was set at $2\theta = 10^\circ$ for all experiments (Fig. 2c). The prismatic sampling gauge volume was defined by the intersection of the incoming beam (defined by slits with a vertical and horizontal opening of $H_v = 1 \text{ mm}$ and $H_h = 1 \text{ mm}$, respectively) and the diffracted beam

(the secondary slits vertical opening is $H_d = 30 \mu m$). The effective gauge volume (corresponding to the immersed volume) length was $L_{GV}^{eff} = 5.9 \text{ mm}$. The detector was a liquid-nitrogen cooled Ge solid-state detector from Canberra (model GL0110). The counting time was 2.5 min per spectrum.

Since the measurements were taken in the near-surface region using the reflection mode, the stress component normal to the investigated surfaces could be assumed to be zero (biaxial plane stress state). Full diffraction patterns were acquired at nine ψ angles. The lattice strain ($\epsilon_{\phi\psi}$) in the ϕ and ψ directions is defined according to:

$$\epsilon_{0^\circ\psi} = 1/2 S_2 * \sigma_{0^\circ} * \sin^2 \psi + S_1 * (\sigma_X + \sigma_Y) = \frac{d_{0^\circ\psi} - d_0}{d_0} \tag{1}$$

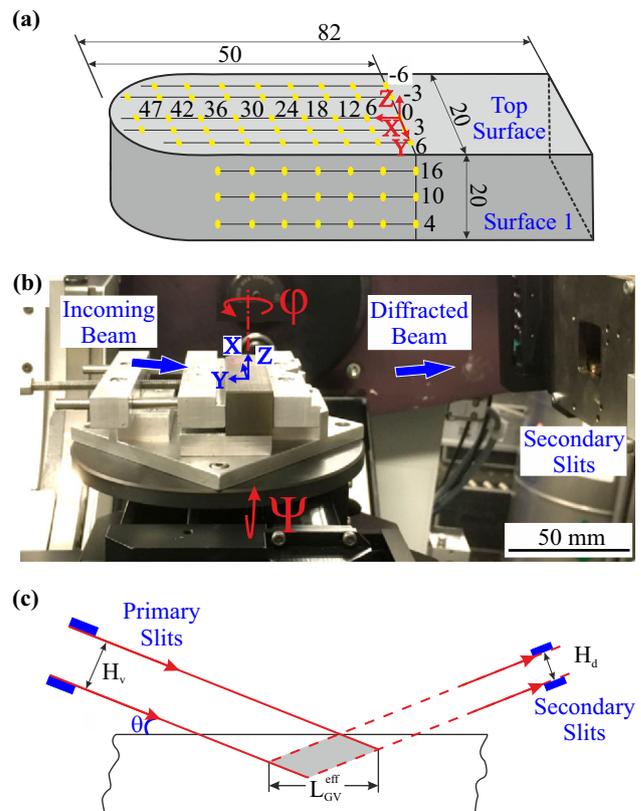

Figure 2 a Illustration of the location of the EDXRD measurement points, as well as the specimen coordinate system (units in mm). b Image of the reflection set-up at EDDI beamline corresponding to the $\phi = 90^\circ$ and $\psi = 0^\circ$ positioning of one of the investigated specimens. c Schematic illustration of the diffraction information area (in grey) corresponding to the set-up utilized during the measurements.

$$\begin{aligned} \varepsilon_{90^\circ\psi} &= \frac{1}{2}S_2 * \sigma_{90^\circ} * \sin^2\psi + S_1 * (\sigma_X + \sigma_Y) \\ &= \frac{d_{90^\circ\psi} - d_0}{d_0}, \end{aligned} \tag{2}$$

where $\varphi = 0^\circ$ and $\varphi = 90^\circ$ correspond to the Y and X principal components in the Top Surface, respectively, S_1 and $\frac{1}{2}S_2$ are the diffraction elastic constants (DEC) [32], and d_0 is the unstrained interplanar lattice spacing. The assumption of a plane stress state supersedes the need for an accurate d_0 value. Since d_0 is simply a multiplying factor of the linear regression slope when calculating σ_φ , it can be approximated by the value measured at zero degrees, $d_{\varphi,\psi=0^\circ}$, giving rise to errors in the stress of only fractions of a percent. In addition, $d_{\varphi\psi}$ is the interplanar spacing measured in the direction described by angles φ and ψ [26]. The DEC used in this study correspond to the Reuß model [29] and are shown in Table 1 (see also the discussion section).

Based on the $d_{\psi}^{hkl} - \sin^2\psi$ linear regression, RS values can be calculated through the following relation:

$$\sigma_\varphi = \frac{m}{\frac{1}{2}S_2}, \tag{3}$$

where m is the slope of the linear regression. When using the $\sin^2\psi$ -method, the information depth to which the measured diffraction signal can be assigned is defined by:

$$\tau_\psi^{hkl} = \frac{\sin\theta}{2\mu(E^{hkl})} * \cos\psi, \tag{4}$$

where $\mu(E^{hkl})$ is the energy-dependent linear absorption coefficient. The maximum information depth is achieved at $\psi = 0$ and denoted τ_0^{hkl} hereafter. The Laplace methods are used to obtain the depth

resolution of each hkl reflection directly from the exponential beam attenuation law for X-rays when passing through matter [41]. All the RS maps shown in the results section correspond to the crystallographic plane (311). This plane was chosen because of its low plastic anisotropy in conventional Ni-base alloys [42]. Note that we generated $\sigma - \tau_0^{hkl}$ plots, instead of generating them with the average $\langle \tau^{hkl} \rangle$, as recommended in [43]; this led to a discrete depth distribution, which coincides with the actual Laplace stress depth. For the 311 reflection, the maximum information depth is $\tau_0^{311} = 42 \mu\text{m}$. The EDDIDAT program system provided by the X-ray CoreLab (HZB) [44] was used for handling the measured data and stress calculation.

In order to compare RS with distortions, Von Mises (VM) stresses were calculated for the Top Surface, according to:

$$\sigma_{VM} = \sqrt{\sigma_X^2 - \sigma_X\sigma_Y + \sigma_Y^2}. \tag{5}$$

Note that both VM RS and distortions are not related to hydrostatic stresses [45].

Distortion and surface roughness evaluation

The Z-displacement of the upper surface of the specimens (i.e., Top Surface) was measured using a white light (diode emitting between 400 and 3400 nm) profilometer (an FRT MicroProf device with an FRT CWL sensor). This device used an interferometer to calculate the distance from the specimen surface to the sensor. The area investigated was $18 \times 60 \text{ mm}^2$ using a scanning speed of $794 \mu\text{m/s}$ and a step size of $20 \mu\text{m}$. The data acquired after removal from the baseplate were post-treated to correct for parallelism defects.

The surface roughness was measured using a Hommel Werke TKL300 system, equipped with a tip of $5 \mu\text{m}$ radius. The surface of the region of interest was $30 \times 8 \text{ mm}^2$. Four lines parallel to the X-direction (test length of $L_t = 15 \text{ mm}$ with $L_c = 2.5 \text{ mm}$ of cut off) were measured at $V_t = 0.5 \text{ mm/s}$ from bottom to top with incremental spacings of $X = 5 \text{ mm}$ and $Y = 2 \text{ mm}$. The roughness values R_a (arithmetic mean height), R_z (maximum height), and R_{max} (maximum peak height) were calculated using the HOMMEL-ETAMIC software according to ISO:4287:210 [46].

Results

Microstructure

The as-manufactured microstructures characterized by SEM in backscattered electron (BSE) mode display similar columnar dendritic cells (width between 0.4 and 0.8 μm) for all three scan strategies (see Fig. 3a,b, where, for the sake of brevity, only the Y-scan and Rot-scan microstructures are given). In the case of the Rot-scan microstructure (Fig. 3b), the dendrite cell growth direction varies across the different regions. This indicates that the heat flow locally varies within the melt pool, even though the overall heat flow is

expected to be approximately parallel to the building direction, as shown in Fig. 3a.

During the solidification of the melt pool, elemental solutes are ejected to dendrite surfaces leading to the localization of alloying elements around the dendrite-cells. The elemental mapping analysis (Fig. 3c) via EDS indicates that the brighter regions surrounding dendritic cells contain higher concentration of the alloying elements Nb, Mo, and Ti. The EDS analysis also indicates (not shown in Fig. 3c) that these regions are depleted of Fe, Cr, and, to a lower extent, Ni. It has been reported that these segregated regions occur at the level of dendritic cells, subgrains (formed by a group of adjacent dendritic cells with

low angle (about $< 5^\circ$) misorientations), and grain boundaries [47, 48]. Some authors also report the presence of nanometric Laves $(\text{Ni,Cr,Fe})_2(\text{Nb,Ti})$ particles within these micro-segregated regions [49–53]. The EDS results presented in this study are in agreement with transmission electron microscopy (TEM) observations shown in [54]. Moreover, scanning transmission electron microscopy elemental maps (STEM-EDS) show heterogeneous distributions of alloying elements (notably for Ti and Al), which are in fact related to the presence of Laves [48, 55] and carbide phases MC $(\text{Nb,Ti})(\text{C,N})$ [53, 56]. Finally, the spherical black dots indicated with red arrows in Fig. 3a,b could be either aluminium oxides [57] or gas porosity [53]. It must be noted that our work is focused on the influence of the different grain structures and textures on RS; therefore, a detailed TEM comparison of the micro-segregation is beyond the scope of this article.

The EBSD orientation maps show that the Y-scan specimen developed columnar grains with a dominance of $\langle 101 \rangle$ -grain orientation (Fig. 3d). The scan-vector direction is clearly noticeable in the XY-plane (Fig. 3g), where thin lines of $\langle 001 \rangle$ -grains are formed in-between the thicker $\langle 101 \rangle$ -grain bands. Note that the cluster of purple small grains observed in the centre of Fig. 3d possibly corresponds to one of the thin bands of $\langle 001 \rangle$ -grains observed in Fig. 3g. The alternating XY-scan also forms columnar grains along the BD, although the dominant grain orientation is $\langle 001 \rangle$ and the vertical length of the grain is reduced (Fig. 3e). The scan-vector direction remains

noticeable in the XY-plane, but the texture intensity is reduced (Fig. 3h), with clusters of $\langle 101 \rangle$ -grains being formed. The Rot-scan specimen exhibits elongated grains (i.e., their aspect ratio is lower than that of columnar grains) with complex shapes and where almost all crystal orientations are observed (Fig. 3f). The XY-plane microstructure appears chaotic in comparison to the other two scanning strategies: the scan-vector direction is barely noticeable and some smaller clusters of $\langle 101 \rangle$ -grains are observed (Fig. 3i).

LXRDR results

The surface stresses along the central line of one half of the specimens Top Surface are shown in Fig. 4a. These measurement locations correspond to the opposite end of the specimen from where the microscopy samples were extracted. σ_x in the As-Built condition shows values in the range of 300–650 MPa, with the highest values corresponding to the Y-scan specimen and the lowest to the Rot-scan specimen (Fig. 4b–d). The thinning of the baseplate induces a significant σ_x relaxation (about 300 MPa) in the region between 0 and 30 mm. The values at the tip region (35 to 50 mm) remain close to those observed in the As-Built condition in all specimens. Again, the highest σ_x values in the Thin-Baseplate condition correspond to the Y-scan specimen (~ 250 MPa against ~ 150 MPa observed in the Rot-scan sample).

The σ_y values in the As-Built condition vary from 400 to 700 MPa, with the XY-scan specimen having the highest values (by only 50 MPa, see Fig. 4e–g) while Y-scan and Rot-scan specimens exhibit similar values. The baseplate thinning does not induce significant RS relaxation in the Y-scan specimen. Nevertheless, a RS relaxation of ~ 50 MPa and ~ 100 MPa is observed in the 0–30 mm region of the XY-scan and Rot-scan specimens, respectively. Note that the σ_y profile in the Thin-Baseplate condition exhibits two undulations at 13 and 32 mm in the Rot-scan specimen. These undulations could result from the grooves generated between hatching stripes during processing (see the white lines in Fig. 4m), which would be more noticeable in the Thin-Baseplate condition due to distortion.

When the VM stresses are compared, it is observed that the Rot-scan sample exhibits the highest relaxation (Fig. 4h–j). This relaxation induces an upward

bending of the specimens (Fig. 4k–m). The Y-scan and Rot-scan specimens exhibit similar distributions in the distortion maps, although the Z-displacement in the tip region (35–50 mm) is slightly higher in the Rot-specimen (10 μm , which is in agreement with the VM results). In contrast, the highest measured Z-displacement of the XY-scan specimen occurs near the opposite end of the specimen, with values that are almost half of those recorded in the tip region of the other two specimens.

EDXRD results

Detailed RS maps of the three principal geometrical components (X, Y, Z(BD)) were obtained for the Thin-Baseplate and Released conditions of the XY-scan and Rot-scan specimens. Due to the limited beamtime available on EDDI, the RS state of the Y-scan specimen was not measured in the Released condition. We

will see that this does not impact the conclusions of our work. The RS plots in the Thin-Baseplate condition of the Y-scan and Rot-scan specimens are taken from reference [25] for comparison with the XY scanning strategy, as well as for the study of the relaxation following release from the baseplate. Regardless of the scanning strategy or condition, the σ_x stress maps generally exhibit a similar tendency, with the highest values being observed in the tip region (30–47 mm, see Fig. 5). In the Thin-Baseplate condition, the RS values vary over all scan strategies in a range between 50 and 500 MPa, with similar distributions in the XY-scan and Rot-scan specimens. In contrast, the Y-scan specimen exhibits higher values (50 MPa on average). The baseplate removal (Released condition) induces a 100 MPa relaxation in the tip region, and the similarity between the XY-scan and Rot-scan specimens is maintained.

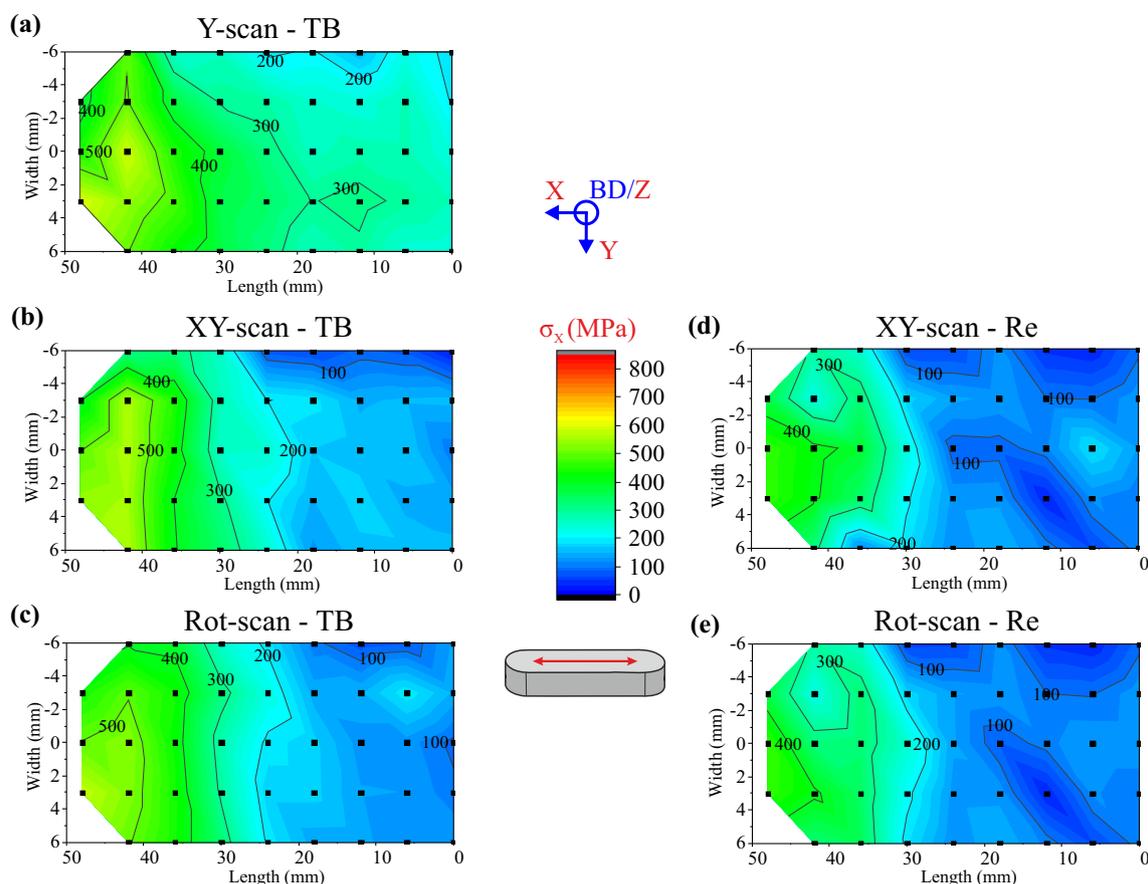

Figure 5 Top Surface RS maps of the X-direction component in the Thin-Baseplate (TB) condition for **a** the Y-scan specimen (replotted from [25]), **b** the XY-scan specimen, and **c** the Rot-scan specimen (replotted from [25]). Top Surface RS maps of the

X-direction component in the Released (Re) condition for **d** the XY-scan specimen and **e** the Rot-scan specimen. The small black squares indicate the location of the measurement points. The average error for all the points is ± 28 MPa.

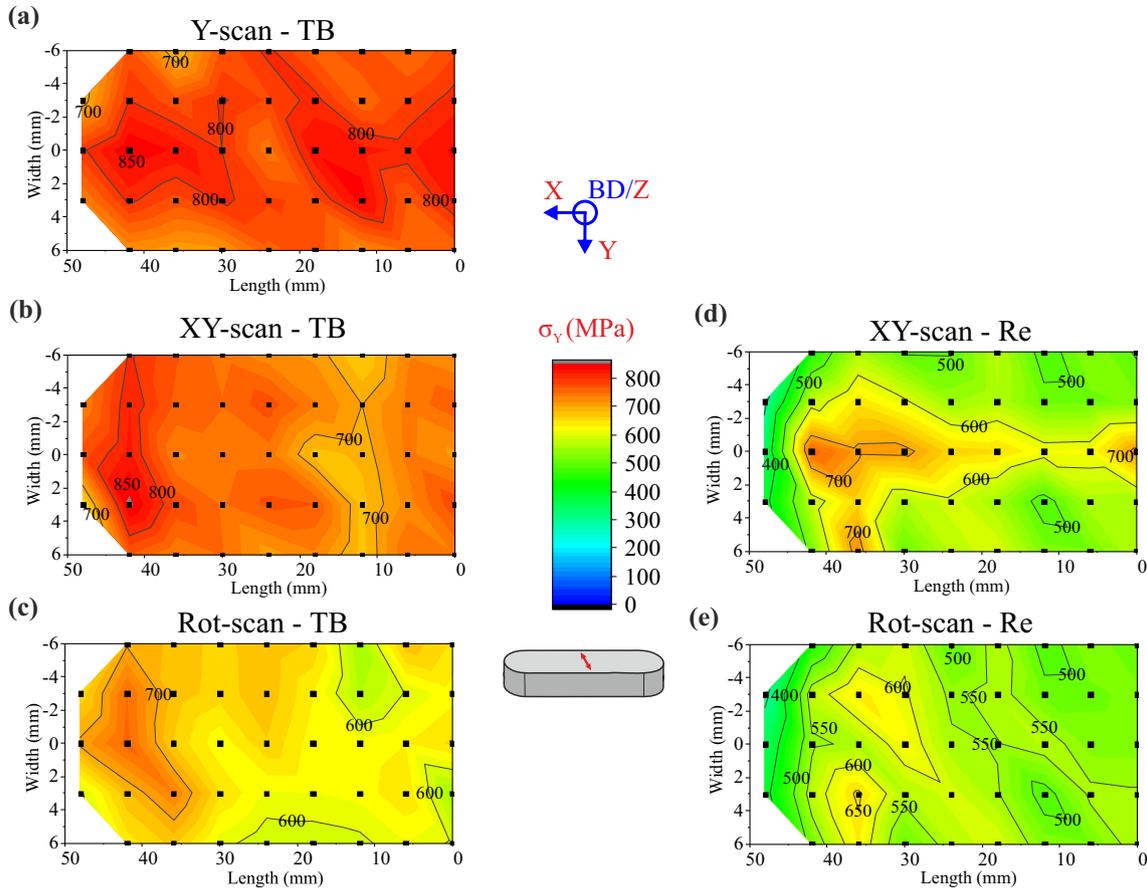

Figure 6 Top Surface RS maps of the Y-direction component in the Thin-Baseplate (TB) condition for **a** the Y-scan specimen (replotted from [25]), **b** the XY-scan specimen, and **c** the Rot-scan specimen (replotted from [25]). Top Surface RS maps of the

Y-direction component in the Released (Re) condition for **d** the XY-scan specimen and **e** the Rot-scan specimen. The average error of the points shown in these maps is ± 34 MPa.

In the 0–25 mm region for the Thin-Baseplate condition, the highest values also correspond to the Y-scan specimen (100 MPa higher than those of the other two specimens, Fig. 5a). A slight asymmetry with respect to the X-axis is observed, principally in the Y-scan specimen. The stress distributions are also similar in the XY-scan and Rot-scan specimens, with the XY-scan values being slightly higher (50 MPa, Fig. 5b–c). A small stress relaxation (> 50 MPa) is observed after the baseplate removal; however, the similarity between the two specimens (XY-scan and Rot-scan) is not affected (Fig. 5d–e). The low degree of σ_x relaxation following the baseplate removal suggests that most of the stress relaxation occurred after the thinning of the baseplate.

The σ_y maps for the Thin-Baseplate condition display points with RS values approaching the yield strength of the material (806 MPa) in the case of

Y-scan and XY-scan specimens (Fig. 6a–c). The Y-scan specimen shows the highest (850–700 MPa) values, and the Rot-scan specimen the lowest (750–600 MPa). In all the specimens, but particularly in the XY-scan and Rot-scan, the highest values tend to be localized at the tip region (35–47 mm).

The baseplate removal induces both an average relaxation of 200 MPa in the XY-scan specimen and a reduction of the homogeneity of the stress distribution (Fig. 6d). The lowest values (400–500 MPa) are in this case observed in the tip region (42–47 mm). A central strip parallel to the X-direction exhibits the highest values (600–750 MPa). This strip is asymmetric, and a small band of high values (600–700 MPa) is observed connecting Surface 1 to the central strip between 35 and 40 mm. The stress values in the rest of the specimen vary between 500 and 550 MPa. The baseplate removal also induces an

average relaxation of about 200 MPa in the Rot-scan specimen (Fig. 6e). The lowest values (400–500 MPa) are also observed at the tip region (42–47 mm), and the values in the rest of the specimen vary between 500 and 550 MPa. Note that neither the stress map in Fig. 6c nor the one in Fig. 6e shows traces of the two undulations observed in Fig. 4m. This indicates that the depth of the grooves induced by the hatching stripes is smaller than the depth (42 μm for 311 reflection) being probed by the X-rays.

The σ_z values in the building direction on the lateral surface of the specimen (Surface 1) in the Thin-Baseplate condition are quite homogeneous (see Fig. 7). Here, the tendency is inverted with respect to the Top Surface; whereby the Rot-scan specimen exhibits the highest values, which in some regions are higher than the bulk yield strength reported for the material. The lowest values (600–700 MPa) are

observed at the bottom of the specimen, where the prism is connected to the thin baseplate. The XY-scan specimen shows intermediate stress values between 500 and 600 MPa, and the Y-scan specimen has lower stresses between 450 and 500 MPa. In this Y-scan specimen, the lowest values are also observed at the bottom of the face.

The baseplate removal induces a σ_z gradient from bottom to top in all the specimens. A relaxation of 300 MPa is observed at the bottom of the Y-scan and XY-scan specimens (Fig. 7e, f), although the values are barely relaxed at the top line. The stress relaxation is more significant near the bottom of the Rot-scan specimen (450 MPa). When compared to the bottom measurement line, the stresses at the top line exhibit a lower degree of stress relaxation (~ 100 MPa).

The σ_x maps of Surface 1 show values close to 0 MPa for all three specimens in the Released

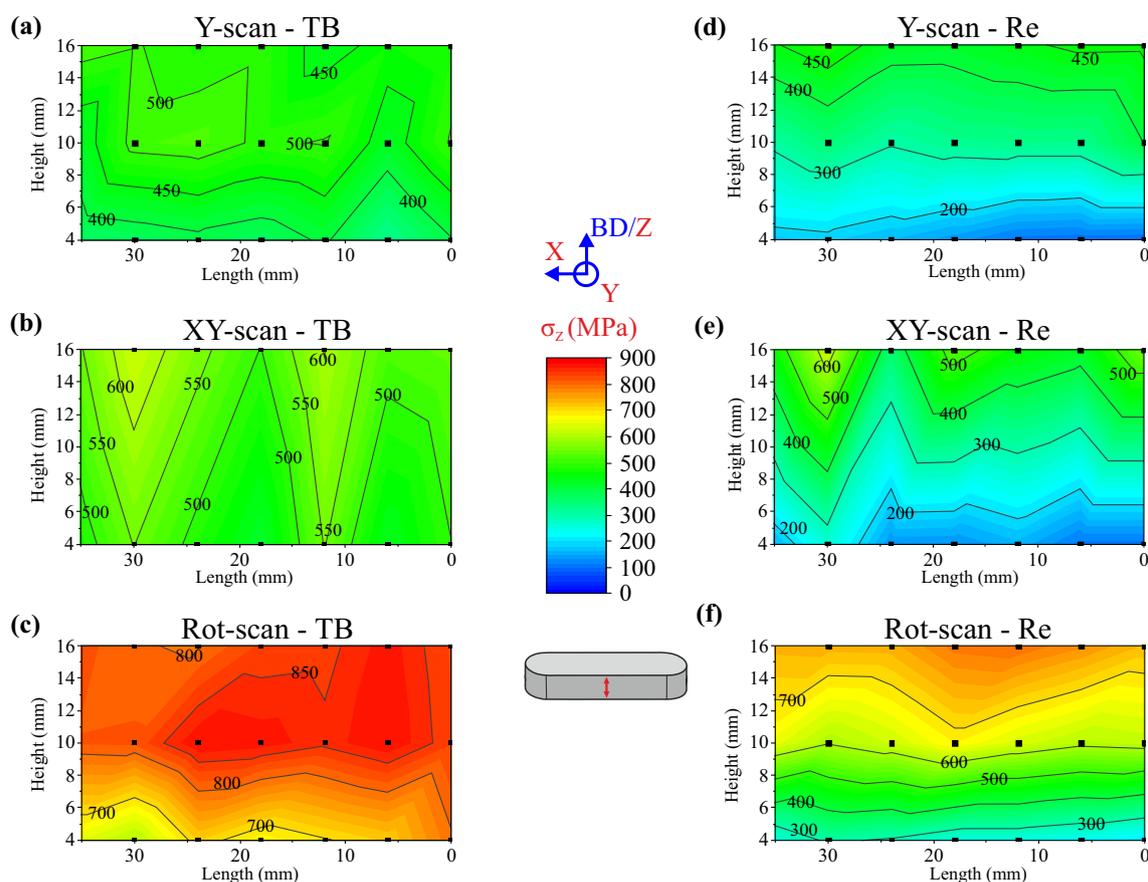

Figure 7 Surface 1 RS maps of the Z-direction component in the Thin-Baseplate (TB) condition for **a** the Y-scan specimen (replotted from [25]), **b** the XY-scan specimen (note that the intermediate points at 10 mm height are missing), and **c** the Rot-scan specimen (replotted from [25]). Surface 1 RS maps of the

Z-direction component in the Released (Re) condition for **d** the Y-scan specimen, **e** the XY-scan specimen (note that the intermediate points at 10 mm height are missing), and **f** the Rot-scan specimen. The average error of the points shown in these maps is ± 27 MPa.

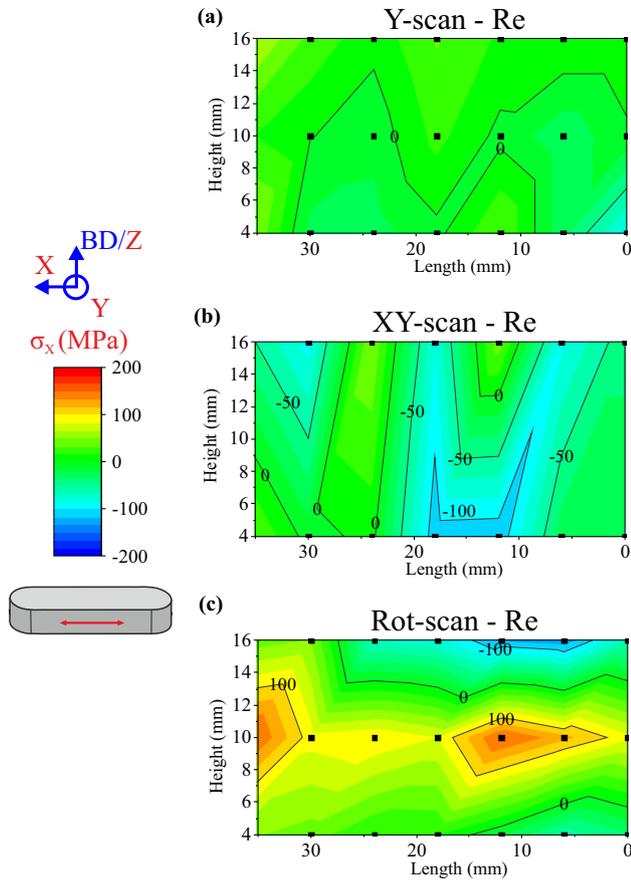

Figure 8 Surface 1 RS maps of the X-direction component in the Released (Re) condition for **a** the Y-scan specimen, **b** the XY-scan specimen (note that the points at 10 mm height are missing), and **c** the Rot-scan specimen. The average error of the points shown in these maps is ± 26 MPa.

condition, particularly in the Y-scan specimen (see Fig. 8; note that the baseplate prevents the evaluation of the X-direction stress component in the Thin-Baseplate condition because the X-ray beam is blocked). The XY-scan specimen shows stresses close to -100 MPa at some point of the bottom and top measurement lines, which could be related to the distortion of the specimen. The Rot-scan specimen exhibits some points with compressive stresses at the top line (also close to -100 MPa) and some points with tensile stresses (close to 150 MPa) at the central line at 10 mm height.

The σ_{VM} maps of Y-scan and XY-scan specimens in the Thin-Baseplate condition display similar stress levels (650 – 700 MPa) with some unevenly distributed localized regions containing higher values (750 MPa, see Fig. 9a–c). The Rot-scan specimen shows overall lower values (500 – 650 MPa). The baseplate removal

induces a similar effect on the XY-scan and Rot-scan specimens, with the most significant relaxation (250 MPa) observed at the tip region (42 – 47 mm, Fig. 9d–e). In the 0 – 40 mm region, an average stress reduction by 100 MPa is observed in both XY-scan and Rot-scan specimens.

Even though the σ_{VM} maps indicate similar level of relaxation for the XY-scan and Rot-scan specimens, the distortion maps show considerable differences. The bending that followed the removal of the thin-baseplate is relatively low in the Y-scan and XY-scan specimens. However, the tendency is inverted in these two specimens when compared to that of Fig. 4h–i; the Y-scan specimen shows the highest Z-displacement values ($16 \mu\text{m}$) in the region nearing the flat end of the specimen, while the XY-scan specimen shows the highest values at the tip ($22 \mu\text{m}$). On the other hand, the Rot-scan specimen exhibits a considerably higher upward Z-displacement of the tip region ($Z = +150 \mu\text{m}$). When the Released condition is compared to the As-Built one, the total Z-displacement occurring at the tip is about $Z = +240 \mu\text{m}$.

Surface roughness results

The surface roughness results of the three specimens are summarized in Table 2. For the lateral Surface 1, the Rot-scan strategy exhibits the lowest surface roughness, while the Y-scanning displays the highest. The up-skin scanning strategy applied on the Top Surface is assumed to lead to similar roughness in the three specimens; thus, only the Top surface of XY-scan sample was measured.

Discussion

Influence of microstructure on diffraction measurements

All $d_{\psi}^{311} - \sin^2\psi$ plots of the EDXRD measurements displayed a linear dependence (Fig. 10, top graphs, where the average error is about ± 30 MPa). The lattice spacing versus $\sin^2\psi$ plots show insignificant ψ -splitting [25] and, therefore, the absence of shear stresses is assumed.

The linearity of the $d_{\psi}^{311} - \sin^2\psi$ plots indicates that the microstructure probed during the EDXRD measurements contains low texture and a reasonably

scan specimen and **e** the Rot-scan specimen. Distortion maps showing the difference in Z-displacement between the Thin-Baseplate and Released conditions for **f** the Y-scan specimen, **g** the XY-scan specimen, and **h** the Rot-scan specimen.

Table 2 Summary of the surface roughness measured on the top and lateral surfaces (Surface 1)

	Top Surface			Surface 1		
	R_a (μm)	R_z (μm)	R_{max} (μm)	R_a (μm)	R_z (μm)	R_{max} (μm)
Y-scan				11.49 ± 1.1	71.7 ± 9.8	84.35 ± 10.8
XY-scan	4.1 ± 0.5	22.0 ± 3.8	30.9 ± 7.4	9.43 ± 1.0	54.96 ± 6.3	74.7 ± 12.4
Rot-scan				4.52 ± 1.1	31.83 ± 9.8	39.8 ± 14.2

small grain size. The integrated intensity of the diffraction peaks ($I_{\text{int}} = \int_{-\infty}^{\infty} I(2\theta)d2\theta$) corroborates this statement, as it shows limited oscillations. Interestingly, the I_{int} profiles are similar for all the investigated specimen surfaces. The integral breadth ($IB = \int I(2\theta)d2\theta / I_{\text{max}}$), which depends on the orientation spread of the diffracting grains, on lattice intragranular strains, and on crystallite sizes, displays a similar tendency and values for all three specimens on the Top Surface. However, the Z-axis values on Surface 1 are observed to be systematically higher than the values measured at the Top Surface. Such an effect seems more related to the different grain sizes. In fact, EBSD investigations of the near-surface regions of the Top Surface and of Surface 1

(Fig. 11) confirms the above conjecture. Significant differences in crystallite sizes and texture between the near-surface and bulk regions appear on all specimens. The up-skin grain structure is similar for all three specimens. The Y-scan specimen is given as an example of the near-surface grain structure: the difference between the Top surface and the bulk microstructure is more noticeable (Fig. 11a). The bulk columnar grain growth is halted at the up-skin border (dashed line in Fig. 11a). From this border upwards, new grains, usually spanning the entire up-skin thickness are formed and both the texture intensity and the grain size are reduced.

On the other hand, the grain structures below Surface 1 exhibit a surface to bulk transition with

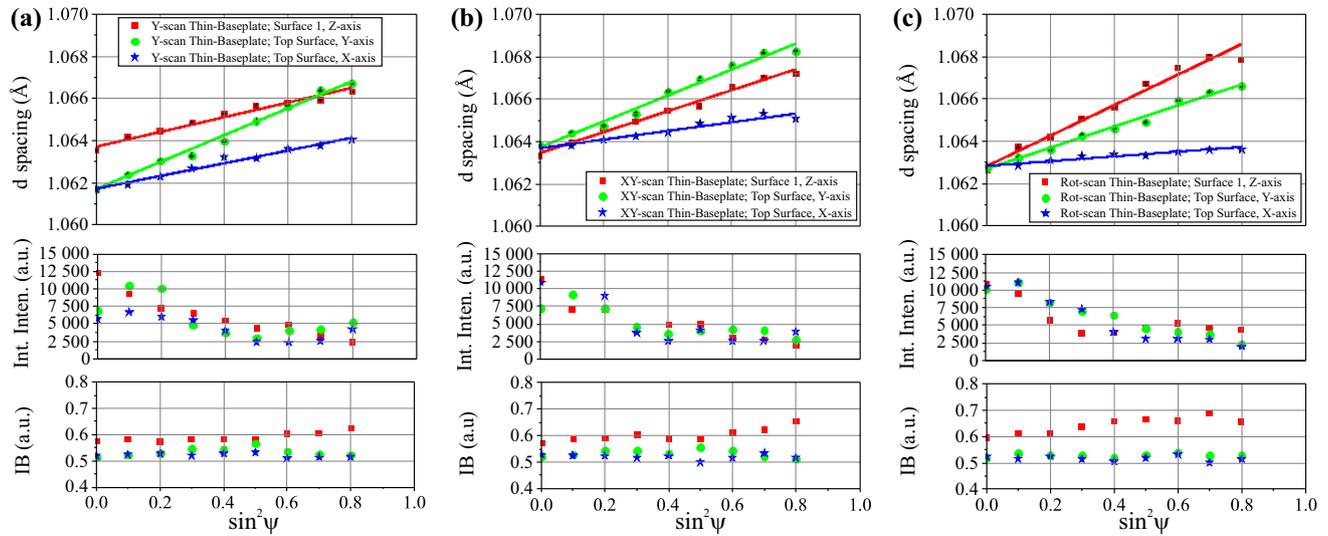

Figure 10 The $d_{\psi}^{311} - \sin^2 \psi$ linear regressions (top), the 311 Integrated Intensity (middle), and the 311 Integral Breadth (bottom) of the principal components (X-, Y-, and Z-directions)

in the Thin-Baseplate condition for **a** the Y-scan specimen, **b** the XY-scan specimen, and **c** the Rot-scan specimen.

significant differences between the specimens. In the Rot-scan specimen (Fig. 11b), there is a first layer below Surface 1 (thickness of $\sim 50 \mu\text{m}$) containing close-to-equiaxed grains. Below this first layer, the grain structure resembles that of the bulk region shown in Fig. 3e. The grain structure of Y-scan specimen can be considered as tri-layered (Fig. 11c,d). The first layer below Surface 1 (of $\sim 150 \mu\text{m}$ thickness) also contains relatively small grains. Next, a layer of $\sim 700 \mu\text{m}$ thickness is formed, which exhibits $\langle 001 \rangle$ -grain orientation dominance and relatively larger columnar grains. From a depth of $850 \mu\text{m}$ inwards, the microstructure shows features similar to those observed in the bulk region (Fig. 3c), i.e., larger columnar grains and $\langle 101 \rangle$ -grain orientation dominance. Interestingly, the first layer of small elongated grains seems not to be present in the XY-scan sample (Fig. 11e, f). Moreover, the transition between the second layer and the bulk microstructure (occurring at $\sim 700\text{--}800 \mu\text{m}$ depth, and indicated with a white arrow in Fig. 11e) is less noticeable than in the Y-scan specimen.

Finally, it is noteworthy that the up-skin grains tend to be larger than the ones observed in the near-surface of Surface 1 (Fig. 11), confirming that a smaller crystallite size seems to be the main reason behind the Top Surface-to-Surface 1 difference observed in the Integral Breadth plots (a gap of 0.1, Fig. 10).

Influence of surface roughness on RS

In general, an increased surface roughness is expected to lead to significantly lower RS magnitudes, as reported in the literature (e.g. [24]). As shown in Fig. 12, the RS state at the first measurement points (corresponding to the $\{111\}$ and $\{200\}$ families of lattice planes) at the Top Surface is not strongly affected by the surface roughness. However, the effect of surface roughness on the near-surface RS state of Surface 1 is clearly noticeable in the $0\text{--}45 \mu\text{m}$ depth, where the stress values tend to progressively increase from the $\{111\}$ plane up to the $\{311\}$ plane. Note that the stress increase is more significant in the Y-scan and XY-scan specimens (about 300 MPa) than in the Rot-scan specimen (about 150 MPa), in agreement with the higher surface roughness measured in these two specimens (Table 2). A plateau is reached in all specimens between the $\{311\}$ and $\{420\}$ planes, indicating that the RS measured in these depths ($45 \mu\text{m}$ and deeper) are no longer influenced by the stress relieving effect of the surface roughness.

Choice of DEC for residual stress analysis

As mentioned in the Introduction, the microstructural and texture characteristics of AM material challenge the common procedures of RS analysis, particularly those using diffraction techniques. In the absence of experimental determination of DEC via

Figure 11 EBSD orientation maps (the scattering vector is along the X-direction) of the near-surface regions for the cases of: **a** the Y-scan specimen below the Top Surface (the dashed black line indicates the approximate location of the border with the up-skin layers (also reported in [25]), **b** the Rot-scan specimen below Surface 1 (reported in [25]), **c** the Y-scan specimen (low magnification) below Surface 1 (note that the surface roughness is cropped-out when setting the indexed region of interest), **d** a higher magnification of the Y-scan image shown in (c) (reported in [25]), **e** the XY-scan specimen (low magnification) below Surface 1 (the white arrow indicates the approximate border between the subsurface region, 150–850 μm , and the bulk microstructure), and **f** a higher magnification on the XY-scan specimen, which corresponds to a region outside of the zone shown in (e).

in situ loading tests, RS has been usually calculated in conventionally manufactured IN718 specimens using the Kröner model [31]. In the case of the present RS results, there are two main reasons that led to the

application of the Reuß model instead of the Kröner model. The first issue when using the Kröner model arises from the high magnitude of the calculated RS. Using this model, near-surface residual stresses of

magnitudes nearing 1200 MPa are calculated, even though the bulk yield strength of the studied material varies between 632 and 806 MPa. Subsequent ageing heat-treatment processes can increase the yield strength up to 1200 MPa through precipitation hardening [58]. However, SEM-BSE observations show that the characteristic interdendritic micro-segregation of the as-manufactured microstructure is preserved in the near-surface, so that such a significant precipitation hardening should be excluded.

There are other factors that can locally increase the yield strength at the near surface. Given than the grain size is relatively smaller in the near-surface region compared to the bulk, a local increase in the yield strength could also be induced by the Hall-Petch effect. Moreover, a near-surface triaxial stress state, as is the case in composites, can also lead to magnitudes of residual stresses higher than the yield strength. However, the origin of such interphase, intergranular (Type II) stresses in the as-manufactured material is not obvious. High interphase stresses between the cell walls (where micro-segregation of alloying elements and high dislocation content at the subgrain boundaries occur) and the cell interior might be able to induce such triaxial state. This point would require further investigation using local techniques (i.e., focused ion beam-digital image correlation (FIB-DIC)) and cannot be taken as a fact here. Even if these effects (Hall-Petch and triaxiality) were combined, it is unlikely that they could induce an increase in the yield strength of about 400 MPa. As shown in Fig. 6a and b, the RS magnitudes calculated

by the Reuß model are only slightly higher (maximum at 870 MPa) than the maximum bulk yield strength values. This slight increase seems much more realistic.

The high *spikiness* of the depth profiles (i.e., jumps between adjacent $\sigma(\tau_0^{hkl})$ values) also gives indication of the unsuitability of using the Kröner model for this material (Fig. 13a). The use of Reuß model has an effect of reducing this *spikiness* on the depth profiles, meaning that this model gives a more accurate description of the intergranular behaviour of the studied materials [43]. It is worth mentioning that in the present calculations the {331} reflection is broadly model-independent, representing a fixed point that does not change its magnitude when the applied grain-integration model is changed.

A plot of the Young's moduli of some reflections against the stiffness anisotropy factor (denoted as $\Gamma_{hkl} = (h^2k^2 + k^2l^2 + l^2h^2)/(h^2 + k^2 + l^2)^2$) is given in Fig. 13b, where the Kröner and Reuß models are compared to experimental E_{hkl} data available in the literature for both conventional and AM Ni-base alloys [59–62]. Note that the Kröner model is suited for quasi-isotropic materials more typical of conventional processing, while the Reuß model seems suited to describe the textured microstructures of IN718 AM materials. One possible explanation for this observation is that in the case of highly textured materials, the crystallites could provide lower constraint to each other and can therefore expand more or less freely [63]; in other words, the columnar microstructure (see Fig. 3d, e) fits well to the ideal microstructure

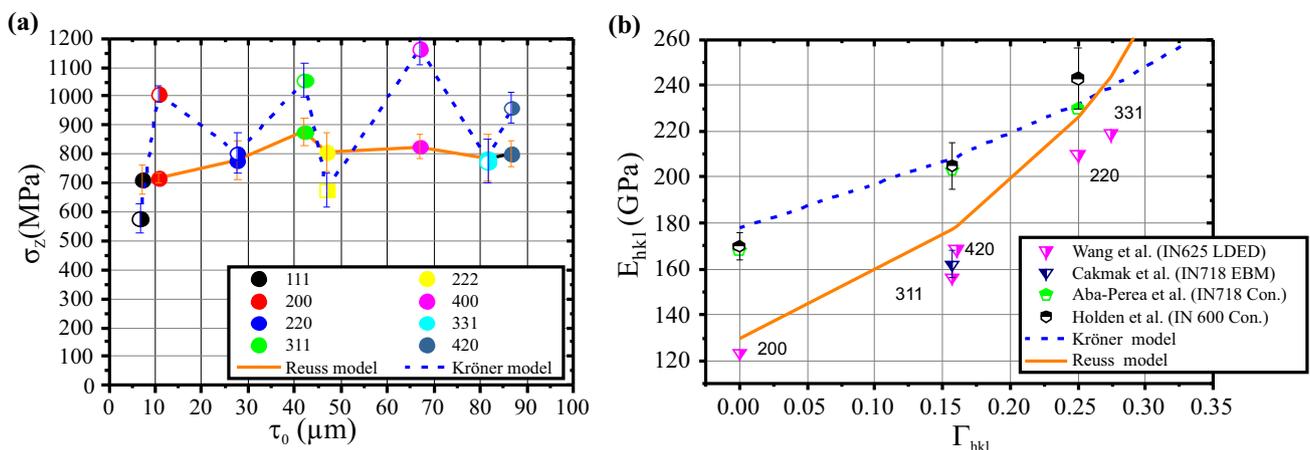

Figure 13 **a** Depth profile plot showing the differences between the use of the Kröner (blue dashed line) and the Reuß (orange solid line) models for DEC calculation in Surface 1 of the Rot-scan

specimen. **b** Plot of Young's moduli of some reflections obtained from the literature [58–62] against the anisotropy factor Γ_{hkl} parallel to an applied uniaxial tensile stress.

schematic of the Reuß model (parallel blocks undergoing the same applied stress).

Since Fig. 13a shows that the Reuß model leads to a lower scatter, it can be concluded that even the finer near-surface grains should also display significant texture effects. Further research is needed to determine if the models developed for materials with preferred texture (i.e., macroscopically anisotropic microstructures) can provide a better description of the IN718 AM intergranular behaviour.

Considerations on the RS results

The results presented in this study show a small asymmetry of the RS fields with respect to the X -axis (see Figs. 5 and 6). The direction of the inert gas flow is proposed as one of the factors that can contribute to the development of this asymmetry [24]. Hence, the influence of the gas flow on RS build-up is a topic of interest for future work.

It is also observed that the σ_x component undergoes a significant relaxation after the baseplate thinning and all specimens exhibit some degree of bending. The removal of the specimen from the thin baseplate mainly relaxes the Z -direction component at the bottom of the lateral Surface 1, creating a stress gradient. As shown in Fig. 9, the XY -plane VM RS maps do not correlate to the degree of distortion observed upon removal from the thin baseplate. This suggests that a larger stress relaxation in the Z -direction most likely exerts the greatest influence on the higher distortion observed in the Rot-scan specimen (Fig. 9h).

There exists a tendency for the σ_x and σ_y values on the Top Surface to decrease from the highest in the Y -scan specimen to the lowest in the Rot-scan specimen. This tendency is inversed on the lateral Surface 1 and the σ_z values decrease from the highest in the Rot-scan specimen to the lowest in the Y -scan specimen. The XY -scan strategy always sits between these other two. Using stress balance considerations, we can interpret the bulk behaviour using the near-surface results. In fact, the lowest near-surface tensile σ_z values measured on Surface 1 should translate into the lowest compressive bulk RS in the Y -scan specimen. In one of our previous works, we have shown that the bulk microstructure of the Y -scan specimen is suspected as the principal factor leading to the lower RS values in the Z -direction of this specimen [25]. It is predicated here that the Y -scan

microstructure should be considered *softer* (i.e., due to a large grain size, it is easier to move and accumulate dislocations and subsequently relax RS) and less *constrained* (i.e., due to texture, the intergranular mismatch induced by the dislocation accumulation is less significant, subsequently leading to a reduced macroscopic plastic heterogeneity) than that of the Rot-scan specimen, where grain boundaries can more easily hinder dislocation movements. Furthermore, the grain structure and RS state of the XY -scan strategy appear to be between those observed in the Y -scan and Rot-scan strategies.

Before continuing with the rationalization of the differences in RS state observed in the three investigated specimens, a brief description on the prior knowledge in the formation of dislocation cell structure is due. Even though the mechanisms controlling dislocation generation during AM are still subjected to debate in the literature [64, 65], it is generally assumed that, independently of how they form, the periodic fluctuations in dislocation density are more stable than uniform arrays [66]. The spatial arrangement of the dislocation cell structure is controlled by the dendrite-cell geometries at the time of solidification [48]. During solidification, some geometrical necessary dislocations are formed at the cell walls to accommodate misorientations between dendrite arms. Also, the post-deposited material is subjected to thermal stresses induced by subsequent deposition passes. Thus, some dislocations would form at the dendrite cell interior, probably ending up entangled at the cell walls as a result of the ongoing thermal cycling. It follows that, presumably, the higher the thermal stresses induced by the processing, the higher the entanglement of dislocations. But how this entanglement affects the built-up of RS?

The role played by the grain structure, texture, as well as the thermal gradients on the built-up of RS is proposed to follow the schematics illustrated in Fig. 14. The grain structure is assumed to be similar in the XY -plane for all three samples (as far as the amount of grain boundaries is concerned, see, for example, Fig. 14a–c). Based on this assumption, all three microstructures would provide similar levels of constraint between the grains. In other words, the accumulation/entanglement of dislocations caused by plastic strain in the XY -plane should be similar in all three microstructures. In this case, we propose that the thermal gradient (TG) controls the build-up of RS in all three specimens (note that the situation

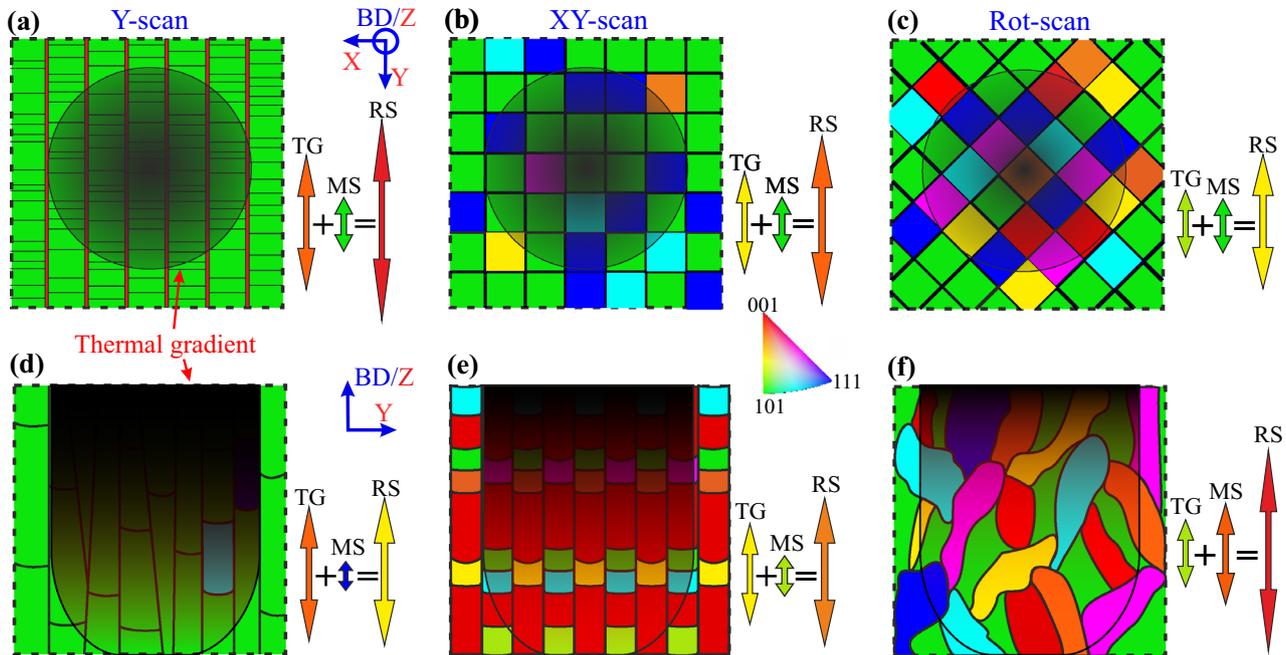

Figure 14 Schematic illustration of the effects of the bulk thermal gradients (TG, indicated with shaded areas) and microstructures (MS, with grain boundaries indicated by solid black lines and grain orientations following the colour code in the inset) on the residual stresses (RS) build-up occurring in the XY-plane of **a** the Y-scan

specimen, **b** the XY-scan specimen, and **c** the Rot-scan specimen; as well as in the ZY-plane of **d** the Y-scan specimen, **e** the XY-scan specimen, and **f** the Rot-scan specimen. The size of the arrows indicates the intensity of each contributing factor.

could be different in the early stages of cooling, where the microstructure does not possess its final features). However, this would not be the case in the ZY-plane, where the RS would notice the differences in microstructure (Fig. 14d–f). Due to smaller columnar grains and lower texture intensity than for the Y-scan strategy, the XY-scan microstructure would be expected to both increase the hindering of dislocation motion (i.e., to reduce the stress relaxation effects during processing) and induce higher intergranular stress mismatch. Finally, the Rot-scan specimen (for the same reasons) would be expected to have the lowest thermal gradient but the highest intergranular stress mismatch and lowest relaxation, thereby leading to the largest RS build-up. In summary, this assumption implies that the slip is activated in such a way that dislocations mainly propagate along the length (BD/Z-axis) of the columnar/elongated grains [48].

It is noted that the shape of the thermal fields in Fig. 14 has been simplified in order to emphasize the differences between the presumed magnitudes of the gradients. The shapes and sizes of the thermal

gradients are expected to vary depending on the process parameters [8, 67].

Even though the above discussion is qualitative, it paves the road to future investigations. For instance, further assessment of the microstructural contribution to the RS build-up would require the use of neutron diffraction for the analysis of the bulk residual stresses and/or some local characterization using techniques such as FIB-DIC [68]. Additionally, comparison of the experimental results with finite element modelling of the process could help to further rationalize the relaxation mechanisms proposed here.

Conclusions

A comprehensive investigation of the influence of three different scanning strategies (X, XY, and Rotation) on the resulting RS state and microstructure as well as on the distortion upon baseplate removal was performed by means of laboratory X-ray diffraction, synchrotron energy-dispersive diffraction, and electron microscopy techniques. The following conclusions can be drawn:

1. The thinning of the baseplate mainly relaxes the X-direction component, σ_x , also leading to the upward bending of specimens (i.e., along the build direction Z).
2. The XY-scan specimen shows intermediate RS values of σ_x and σ_y at the Top Surface and of σ_z at the lateral surface (Surface 1), when compared to the Y-scan and Rot-scan specimens. At the Top Surface, the RS (σ_x and σ_y) magnitudes are observed to be highest for the Y-scan specimen. At Surface 1, the RS (σ_z) magnitudes are highest for the Rot-scan specimen.
3. The stress relaxation upon Thin-Baseplate removal is more significant for σ_z at Surface 1, where a stress gradient in the Z-direction forms to comply with changed boundary conditions.
4. The specimens in the Released condition retain a considerable amount of RS, although the X-direction stress in the lateral surfaces practically vanishes.
5. The distortion in the Released condition is the highest for the Rot-scan specimen, likely induced by the higher σ_z values observed on the Surface 1 of this specimen.
6. The grain structures and intensity of texture observed in the bulk vary from specimen to specimen, although the interdendritic micro-segregation is considered similar in all specimens and regions investigated.
7. Finer grain sizes and lower texture in the near-surface regions yield close-to-linear $\sin^2\psi$ -scans. Due to the up-skin processing, all three specimens show similar microstructures below the Top Surface. In contrast, the microstructure below Surface 1 varies with the scanning strategy.
8. The Reuß model for DEC calculation is considered more suited than the Kröner model to describe the intergranular behaviour of IN718 AM materials, since it yields more realistic RS values in this study and displays better agreement than Kröner for DEC experimental data reported in the literature on AM Ni-base alloys.

Acknowledgements

Gratitude is expressed to Manuela Klaus and Christoph Genzel (HZB, Berlin, Germany) for their

expertise and scientific guidance during the synchrotron experiments at EDDI beamline, in BESSY II. Siemens AG Power and Gas, Berlin, Germany, is acknowledged for the production of the studied material. F. Falk and R. Saliwan-Neumann are acknowledged for his assistance during microscopy work. K. Zieger is also acknowledged for his contribution to the surface roughness measurements.

Author contributions

Conceptualization: All the authors worked on the content of the paper. Investigation: ISM, TF, TM, AU, and DA were involved in the synchrotron X-ray energy-dispersive diffraction experiments and/or subsequent post-treatment of the acquired data. AK performed the laboratory XRD measurements. RH performed the distortion measurements. ISM analysed all the data and AE assisted with the rationalization. Writing—review and editing: ISM wrote and edited the manuscript, which was revised and commented by TM, AK, AE, and GB.
