# Contributions to General Mixed Integer Knapsack Problems 

Alexander Martin Robert Weismantel*

#### Abstract

This paper deals with a general mixed integer knapsack polyhedron for which we introduce and analyze a new family of inequalities. We discuss the value of this family both from a theoretic and a computational point of view.

Keywords: knapsack problem, mixed integer programming, polyhedral combinatorics.

## 1 Introduction

Various classical combinatorial optimization problems become today tractable with polyhedral methods. Indeed, the last decade has emerged a large number of results that play the basis of modern cutting plane algorithms for many combinatorial optimization problems. On the other hand, quite little research has been carried out that deals with a polyhedral study of general mixed integer programming models of the form

$$
\max c^{T} x+d^{T} y: A x+B y \leq \alpha, x \in \mathbb{Z}^{n}, y \in \mathbb{R}^{q}
$$

with matrices $A \in \mathbb{Z}^{m \times n}, B \in \mathbb{Z}^{m \times q}$ and vectors $\alpha \in \mathbb{Z}^{m}, c \in \mathbb{Z}^{n}$ and $d \in \mathbb{Z}^{q}$. For quite a long time, Gomory cutting planes [G60] have been and still are the main ingredient for current cutting plane implementations.

The situation changes when we restrict our attention to general mixed $0 / 1$ programming problems, i.e., problems for which all integer variables are bounded by zero and one. For such problems, the disjunctive programming approach (see, for instance [B75]), the method of lift and project (see, for instance [BCC93]) and flow cover inequalities introduced in [PRW85] support the cutting plane phase of current solvers for mixed integer programming problems.

This paper is an extension of a paper of the second author about the $0 / 1$ knapsack polytope [W97]. We deal with the polyhedron associated with the feasible solutions of a general mixed integer knapsack problem in which all variables may have arbitrary, but finite bounds. We introduce in Section 2 our model and the family of weight inequalities that turn out to be valid for this model. Section 3 deals with an analysis of weight inequalties in special cases. We present a family of knapsack polyhedra for which essentially weight inequalities are sufficient to describe the associated polyhedron. Computational experiments with this family of inequalities are reported in Section 4.

[^0]
## 2 The Family of Weight Inequalities

Let $N, Q$ be mutually disjoint finite subsets of $\mathbb{N} \backslash\{0\}$ of cardinality $n$ and $q$, respectively. For given vectors $a \in \mathbb{N}^{n}, b \in \mathbb{N}^{q}, u \in \mathbb{N}^{n+q}$ and a number $\alpha \in \mathbb{N} \backslash\{0\}$, we investigate

$$
\begin{align*}
X(N, Q):= & \left\{(x, y) \in \mathbb{Z}^{n} \times \mathbb{R}^{q}:\right.  \tag{2.1}\\
& \sum_{i \in N} a_{i} x_{i}+\sum_{i \in Q} b_{i} y_{i} \leq \alpha \\
& 0 \leq(x, y) \leq u\},
\end{align*}
$$

where we use the notation $(x, y)$ to abbreviate $\left(x^{T}, y^{T}\right)^{T}$. By definition, the members in $X(N, Q)$ are feasible solutions of the mixed integer knapsack problem with general lower and upper bounds on the variables,

$$
\max c^{T} x+d^{T} y:(x, y) \in X(N, Q)
$$

In this section we study the polyhedron $\operatorname{conv}(X(N, Q))$. There is one elementary family of inequalities that is valid for $\operatorname{conv}(X(N, Q))$ that under certain assumptions suffices to describe $\operatorname{conv}(X(N, Q))$. We call this family weight inequalities.

Definition 2.1. For $T \subseteq N$ and $S \subseteq Q$ such that $\sum_{i \in T} a_{i} u_{i}+\sum_{i \in S} b_{i} u_{i}<\alpha$, we denote by

$$
r(T, S):=\alpha-\sum_{i \in T} a_{i} u_{i}-\sum_{i \in S} b_{i} u_{i}
$$

the residual knapsack capacity of the feasible solution $(x, y) \in X(N, Q)$ with $x_{i}:=u_{i}$ for all $i \in T, y_{i}:=u_{i}$ for all $i \in S, x_{i}, y_{i}:=0$, otherwise. The weight inequality with respect to $T, S$ is the inequality

$$
\sum_{i \in T} a_{i} x_{i}+\sum_{i \in S} b_{i} y_{i}+\sum_{i \in N \backslash T}\left(a_{i}-r(T, S)\right)^{+} x_{i} \leq \alpha-r(T, S),
$$

where $v^{+}:=\max \{0, v\}$ for $v \in \mathbb{R}$.
The name weight inequality reflects that the coefficients of the variables in $T \cup S$ equal their original weights. The coefficients of the (rational) variables in $Q \backslash S$ are zero. Likewise, the coefficient of an (integer) variable $i$ in $N \backslash T$ is zero, if the weight $a_{i}$ is smaller than $r(T, S)$. Otherwise, it is the weight $a_{i}$ reduced by the value $r(T, S)>0$.

Example 2.1. Consider the convex hull of tuples of vectors $(x, y) \in\{0,1\}^{6} \times$ $[0,1]^{2}$ that satisfy

$$
x_{1}+x_{2}+x_{3}+x_{4}+3 x_{5}+4 x_{6}+2 y_{1}+3 y_{2} \leq 4
$$

Setting $T:=\{2,3,4\}, S=\emptyset$, we obtain that $r(T, S)=1$. Then $a_{1}-r(T, S)=0$, $a_{5}-r(T, S)=2$ and $a_{6}-r(T, S)=3$. The weight inequality associated with T, $S$ reads

$$
x_{2}+x_{3}+x_{4}+2 x_{5}+3 x_{6} \leq 3 .
$$

For $T:=\{1\}, S=\{1\}$, the weight inequality associated with $T, S$ reads

$$
x_{1}+2 y_{1}+2 x_{5}+3 x_{6} \leq 3
$$

Weight inequalities are valid for the mixed integer knapsack polyhedron $\operatorname{conv}(X(N, Q))$.

Proposition 2.1. For $T \subseteq N, S \subseteq Q$ such that $\sum_{i \in T} a_{i} u_{i}+\sum_{i \in S} b_{i} u_{i}<\alpha$, the weight inequality with respect to $T, S$ is valid for $\operatorname{conv}(X(N, Q))$.

Proof. Let $(x, y) \in X(N, Q)$. If $\sum_{i \in N \backslash T: a i>r(T, S)} x_{i}=0$, then by definition,

$$
\sum_{i \in T} a_{i} x_{i}+\sum_{i \in S} b_{i} y_{i}+\sum_{i \in N \backslash T}\left(a_{i}-r(T, S)\right)^{+} x_{i} \leq \alpha-r(T, S) .
$$

Otherwise, $\sum_{i \in N \backslash T: a_{i}>r(T, S)} x_{i} \geq 1$ holds. We obtain

$$
\begin{array}{ll}
\sum_{i \in T} a_{i} x_{i}+\sum_{i \in S} b_{i} y_{i}+\sum_{i \in N \backslash T}\left(a_{i}-r(T, S)\right)^{+} x_{i} & \leq \\
\sum_{i \in N} a_{i} x_{i}+\sum_{i \in Q} b_{i} y_{i}-r(T, S) \sum_{i \in N \backslash T: a i>r(T, S)} x_{i} \leq \\
\alpha-r(T, S) .
\end{array}
$$

This proves the statement.
The family of weight inequalities subsume various preprocessing operations that software packages have sometimes incorporated for tightining integer programming formulations.

One such example is the following coefficient-reduction operation. For $u, \alpha \in$ $\mathbb{N}, u<\alpha$ consider the feasible set

$$
\mathcal{F}:=\left\{x \in \mathbb{Z}^{2}: 0 \leq x_{1} \leq u, 0 \leq x_{2} \leq 1, x_{1}+\alpha x_{2} \leq \alpha\right\}
$$

It is easy to see that this feasible set has an equivalent formulation as

$$
\mathcal{F}=\left\{x \in \mathbb{R}^{2}: 0 \leq x_{1} \leq u, 0 \leq x_{2} \leq 1, x_{1}+u x_{2} \leq u\right\}
$$

The inequality $x_{1}+u x_{2} \leq u$ is a weight inequality (w.r.t. $T=\{1\}, S=\emptyset$ ) that is valid for $\operatorname{conv}(\mathcal{F})$. In fact, this operation of tightining coefficients generalizes to the following situation.

Consider the constraint

$$
\begin{equation*}
\sum_{i \in R} x_{i}+\sum_{j \in F} \alpha x_{j} \leq \alpha \tag{2.2}
\end{equation*}
$$

where $F$ is a subset of $0 / 1$ variables, $R$ is a subset of integer variables, each variable $i \in R$ having an upper bound $u_{i}$ and $\sum_{i \in R} u_{i}<\alpha$. The constraint (2.2) may be replaced by

$$
\begin{equation*}
\sum_{i \in R} x_{i}+\sum_{j \in F}\left(\sum_{i \in R} u_{i}\right) x_{j} \leq \sum_{i \in R} u_{i} \tag{2.3}
\end{equation*}
$$

The inequality (2.3) is a weight inequality for

$$
P:=\operatorname{conv}\left\{x \in \mathbb{Z}^{R} \times\{0,1\}^{F}: x \text { satisfies }(2.2)\right\}
$$

In fact, $P$ may be described as

$$
P=\operatorname{conv}\left\{x \in \mathbb{Z}^{R} \times\{0,1\}^{F}: x \text { satisfies }(2.3)\right\}
$$

Investigating the latter formulation, one recognizes that all the facets of $P$ are induced by the family of weight inequalities,

$$
\begin{equation*}
x_{i}+\sum_{j \in F} u_{i} x_{j} \leq u_{i} \text { for all } i \in R \tag{2.4}
\end{equation*}
$$

This system of inequalities together with lower and upper bound constraints on the variables describes $P$.

A special case of this latter preprocessing operation may also be found under the name probing.

## 3 A Family of Mixed Integer Knapsack Polyhedra

Having introduced weight inequalities for a general mixed integer knapsack problem, we indicate in this and the subsequent section that these inequalities are useful, at least in special cases. This section is devoted to this question from a more theoretical point of view. We demonstrate that there is a family of general mixed integer knapsack problems for which weight inequalities are needed in order to describe the associated polyhedron. This family of problems is defined as follows.

Let $N_{1}, N_{2}, Q$ be mutually disjoint finite subsets of $\mathbb{N} \backslash\{0\}$ of cardinality $n_{1}$, $n_{2}$ and $q$, respectively. Let $n=n_{1}+n_{2}$. For $\alpha \in \mathbb{N} \backslash\{0\}$ and given vectors $a \in \mathbb{N}^{n}$ such that $a_{i}=1$ for all $i \in N_{1}$ and $a_{i} \geq\left\lfloor\frac{\alpha}{2}\right\rfloor+1$ for all $i \in N_{2}, b \in \mathbb{N}^{q}$ and $u \in \mathbb{N}^{n+q}$, we study the mixed integer knapsack polyhedron $\operatorname{conv}\left(X\left(N_{1} \cup N_{2}, Q\right)\right)$ defined in (2.1).

Theorem 1. The system of all weight inequalities w.r.t. subsets $T, S$ of $N_{1}$ and $Q$, respectively, the set of all lower and upper bounds, and the two inequalities

$$
\begin{array}{ll}
\sum_{i \in N_{2}} x_{i} & \leq 1 \\
\sum_{i \in N_{1}} x_{i}+\sum_{i \in N_{2}} a_{i} x_{i}+\sum_{i \in Q} b_{i} y_{i} & \leq \alpha
\end{array}
$$

describe $\operatorname{conv}\left(X\left(N_{1} \cup N_{2}, Q\right)\right)$ if $a_{i}=1$ for all $i \in N_{1}$ and $a_{i} \geq\left\lfloor\frac{\alpha}{2}\right\rfloor+1$ for all $i \in N_{2}$.

Proof. Obviously, the system of inequalities is valid for $\operatorname{conv}\left(X\left(N_{1} \cup N_{2}, Q\right)\right)$, see Proposition 2.1. It remains to show that it suffices to describe conv $\left(X\left(N_{1} \cup\right.\right.$ $\left.\left.N_{2}, Q\right)\right)$. To see this, first notice that $\operatorname{conv}\left(X\left(N_{1} \cup N_{2}, Q\right)\right)$ is full dimensional. Let the inequality $c^{T} x+d^{T} y \leq \gamma$ induce a facet $F$ of $\operatorname{conv}\left(X\left(N_{1} \cup N_{2}, Q\right)\right)$. We assume that $c^{T} x+d^{T} y \leq \gamma$ is not a positive multiple of one of the nonnegativity constraints, the upper bound constraints and the knapsack inequality. Since $a, b>0$, we have that $c_{i}, d_{j} \geq 0$ for all $i \in N_{1} \cup N_{2}, j \in Q$. We define $T:=\left\{i \in N_{1}: c_{i}>0\right\}$ and $S:=\left\{i \in Q: d_{i}>0\right\}$. There are three claims that we need in order to show the statement,

1. $\sum_{i \in T} u_{i}+\sum_{i \in S} b_{i} u_{i}<\alpha$;
2. The vector $\left(x^{0}, y^{0}\right)$ with $x_{i}^{0}:=u_{i}$ for all $i \in T \cup S, x_{i}^{0}:=0$, otherwise is contained in $F$;
3. $c_{i}=0$ for all $i \in N_{1} \backslash T, c_{i}=0$ for all $i \in\left\{j \in N_{2}: a_{j} \leq r(T, S)\right\}$ and $d_{i}=0$ for all $i \in Q \backslash S$.

Claim 1 follows by noting that if $\sum_{i \in T} u_{i}+\sum_{i \in S} b_{i} u_{i} \geq \alpha$ would hold, then every point in $X\left(N_{1} \cup N_{2}, Q\right) \cap F$ would satisfy the equation $\sum_{i \in N_{1}} x_{i}+$ $\sum_{i \in N_{2}} a_{i} x_{i}+\sum_{i \in Q} b_{i} y_{i}=\alpha$. (Recall that $a_{i}=1$ for all $i \in T$.) This contradicts our assumption that $F$ is not induced by the original knapsack inequality.

Note that Claim 1 implies $\left(x^{0}, y^{0}\right) \in X\left(N_{1} \cup N_{2}, Q\right)$ and $r(T, S)>0$.
We may assume that Claim 2 holds, for if not, then every integral point in $F$ would satisfy the equation $\sum_{i \in N_{2}} x_{i}=1$. Therefore, $F$ must be the facet induced by this inequality.

Denoting by $e^{i}$ the $i$-th unit vector we derive from Claims 1 and 2 that $\left(x^{0}, y^{0}\right)+e^{i} \in X\left(N_{1} \cup N_{2}, Q\right)$ for all $i \in N_{1} \backslash T$ and for all $i \in\left\{j \in N_{2}\right.$ : $\left.a_{j} \leq r(T, S)\right\}$. Moreover, $\left(x^{0}, y^{0}\right)+e^{i} \in F$. Accordingly, $\left(x^{0}, y^{0}\right)+\frac{1}{b i} e^{i} \in$ $X\left(N_{1} \cup N_{2}, Q\right)$ and $\left(x^{0}, y^{0}\right)+\frac{1}{b i} e^{i} \in F$ for all $i \in Q \backslash S$. This shows Claim 3.

We define a function $f: N_{2} \mapsto \mathbb{R}^{+}$by setting

$$
\begin{align*}
f(i):=\min & \sum_{j \in T} c_{j} z_{j}+\sum_{j \in S} d_{j} t_{j}, \\
\mathrm{s.t.} & \sum_{j \in T} z_{j}+\sum_{j \in S} b_{j} t_{j}=a_{i}-r(T, S),  \tag{3.1}\\
& 0 \leq z_{j} \leq u_{j}, z_{j} \in \mathbb{Z} \text { for all } j \in T, \\
& 0 \leq t_{j} \leq u_{j}, t_{j} \in \mathbb{Q} \text { for all } j \in S
\end{align*}
$$

Note that a solution of problem (3.1) attains the minimal value (w.r.t. $c, d$ ) by which the solution $\left(x^{0}, y^{0}\right)$ must be decreased in order to obtain a feasible solution with $x_{i}=1$. We show
4. $c_{i}=f(i)$ for all $i \in N_{2}$.

To see that $c_{i} \leq f(i)$, let $(z, t)$ be a solution of the program (3.1). The vector $\left(x^{i}, y^{i}\right)$ defined as $x_{j}^{i}=x_{j}^{0}-z_{j}$ for all $j \in T, x_{j}^{i}=0$ for all $j \in N_{2} \backslash\{i\}, x_{i}^{i}=1$, $y_{j}^{i}=y_{j}^{0}-t_{j}$ for all $j \in S$ and $y_{j}^{i}=0$ for all $j \in Q \backslash S$ satisfies the condition that $\left(x^{i}, y^{i}\right) \in X\left(N_{1} \cup N_{2}, Q\right)$. This implies that $c_{i} \leq f(i)$.

To see that $c_{i} \geq f(i)$ note that $F$ is a facet. Therefore, there exists, for every $i \in N_{2}$, a feasible point $(x, y) \in F$ such that $x_{i}=1$. We may assume that $x_{j}=0$ for all $j \in N_{1} \cup N_{2}$ with $c_{j}=0$. Accordingly, we can assume that $y_{j}=0$ for all $j \in Q$ such that $d_{j}=0$. Since $\left(x^{0}, y^{0}\right) \in F, c^{T}\left(x-x^{0}\right)+d^{T}\left(y-y^{0}\right)=0$. Setting $z_{j}:=x_{j}^{0}-x_{j}$ for all $j \in T$ and $t_{j}:=y_{j}^{0}-y_{j}$ for all $j \in S$, we obtain that $(z, t)$ is a feasible solution of (3.1). Taking into account that both $(x, y)$ and $\left(x^{0}, y^{0}\right)$ are feasible solutions contained in $F$, we obtain $c_{i}=\sum_{j \in T} c_{j} z_{j}+\sum_{j \in S} d_{j} t_{j} \geq f(i)$.

It follows that every $x$ in $F \cap X\left(N_{1} \cup N_{2}, Q\right)$ also satisfies the weight inequality associated with $T, S$ as an equation. Since $F$ is a facet, the inequality $c^{T} x+$ $d^{T} y \leq \gamma$ (after appropriate scaling) must coincide with the weight inequality with respect to $T, S$.

In the more general case when we neglect the condition that $a_{i} \geq\left\lfloor\frac{\alpha}{2}\right\rfloor+1$ for all $i \in N_{2}$, the associated polyhedron $\operatorname{conv}\left(X\left(N_{1} \cup N_{2}, Q\right)\right)$ is not necessarily described only by weight inequalities. However, weight inequalities are still needed in a minimal description of $\operatorname{conv}\left(X\left(N_{1} \cup N_{2}, Q\right)\right)$, because they induce facets. This follows from

Proposition 3.1. Let $\operatorname{conv}(X(N, Q))$ be the mixed integer knapsack polyhedron defined in (2.1). A weight inequality w.r.t. subsets $T, S$ of $N$ and $Q$ defines a facet of $\operatorname{conv}(X(N, Q))$ if $r(T, S)>0$ and $a_{i}=1$ for all $i \in T$.

## 4 Experiments with Weight Inequalities

In this section we investigate whether weight inequalities occur in real world models and examine to which extend they help in solving practical problems faster. We use the library of mixed integer programs MIPLIB ${ }^{1}$ as our test set. To answer both questions we have incorporated weight inequalities into a general mixed integer programming solver, called SIP. SIP is an LP-based branch-andbound algorithm and is currently under our development; a description of its features will be published in a forthcoming paper. Input of our computational tests are the MIPLIB problems, presolved by SIP. We interpret each single inequality of the constraint system as a mixed integer knapsack problem. To meet the requirements in (2.1) all coefficients have to be positive, which can easily be obtained by complementing variables. In addition, all variables with a non-zero coefficient in the particular inequality must have finite lower and upper bounds. Moreover, we require that the support of the inequality is at least three, otherwise a complete description of the mixed integer knapsack polytope associated with this inequality is already obtained after presolve, see the discussions in Section 2. Finally, we do not consider inequalities whose coefficients are solely $0, \pm 1$. For convenience we call inequalities satisfying all these requirements feasible. It turns out that 48 out of 68 MIPLIB problems contain feasible inequalities. For each of these 48 instances and for each feasible inequality we try to derive weight inequalities that cut off the current optimal LP solution. To do so, we must solve the following separation problem.

Problem 4.1. Given $a \in \mathbb{N}^{n}, b \in \mathbb{N}^{q}, \alpha \in \mathbb{N}$ and $(x, y) \in \mathbb{Q}^{n+q}$. Decide whether $(x, y)$ satisfies all weight inequalities of $\operatorname{conv}(X(N, Q))$. If not, find one that is violated by $(x, y)$.

Problem 4.1 turns out to be $\mathcal{N} \mathcal{P}$-hard. Therefore, we developed a heuristic which proceeds along the following lines.

## Algorithm 4.2.

1. Sort the components of the vector $\left(\left(x^{*}, y^{*}\right)-u\right) \circ(a, b)$ in increasing order, where $\left(x^{*}, y^{*}\right)$ is the current optimal LP solution, and for vectors $v, w$ the symbol $v \circ w$ denotes the vector with components $v_{i} w_{i}$.
2. Construct sets $T \subseteq N$ and $S \subseteq Q$ following the order of Step 1 in a greedy fashion as long as $\sum_{i \in T} u_{i} a_{i}+\sum_{i \in S} u_{i} b_{i}<\alpha$.
3. Check whether the weight inequality w.r.t. $S, T$ is violated.

We have experimented with different strategies to determine sets $S$ and $T$. The ordering of the variables according to their contribution to the slack of the inequality ( $=$ left hand side - right hand side) as outlined in Step 1 turned out to perform best. First test runs with this heuristic show that many inequalities are found whose slack is positive. The question arises which of these inequalities should be added to the current LP. Taking all with positive slack is not a good choice, since weight inequalities tend to have high coefficients. We performed several tests on how to accomplish this fact and our final choice fell on the following. We add a violated inequality to the LP if the slack divided by the

| Example | SIP with kn |  |  | SIP with kn + wi |  |  |  |
| :--- | ---: | ---: | ---: | ---: | ---: | ---: | ---: |
|  | B\&B | kn | Time | B\&B | kn | wi | Time |
| bell3b | 14301 | 0 | 125.6 | 10948 | 0 | 111 | 98.4 |
| bell5 | 2456 | 0 | 15.1 | 8542 | 0 | 15 | 39.5 |
| enigma | 7224 | 2625 | 156.7 | 3631 | 1425 | 1 | 64.1 |
| gt2 | 68547 | 0 | 623.9 | 264 | 0 | 1 | 2.5 |
| mitre | 1143 | 2325 | 2756.1 | 673 | 2117 | 741 | 1930.2 |
| noswot | 99366 | 0 | 3600.0 | 95418 | 0 | 540 | 3600.0 |

Table 1: A comparison of SIP with and without weight inequalities
absolute value of the largest coefficient is at least $\epsilon=0.05$. Table 4 shows some results.

We made the following comparison. We used SIP with default settings of the parameters and turned on the options strong branching and knapsack separation; strong branching is a branching strategy introduced by CPLEX ${ }^{2}$ that is in particular useful for difficult MIP problems; separation of knapsack inequalities is applied to all inequalities containing only $0 / 1$ variables. (How these inequalities are separated is of no importance for this test.) We compared the strategy to the one where we separate weight inequalities in addition. We tested both alternatives for all 48 MIPLIB problems that contain feasible inequalities. For just the six problems that we list in Table 4, a significant difference in time or solution quality occured. Columns 2 through 4 show the number of branch-and-bound nodes, the number of added knapsack inequalities, and the time (measured on a SUN Enterprise 3000) needed to solve the problem using SIP without weight inequalities. Columns 5 through 8 present the corresponding numbers when weight inequalities are separated. Column 7 contains information about the number of weight inequalities added to the linear programs. We stoped after 3600 CPU seconds. Within this time limit we could not solve example noswot to optimality. For problem noswot weight inequalities help to find a significantly better solution, a phenomenon we do not have an explanation for. For the other five models we find the optimal solution with any of the two strategies. With the exception of bell5 it pays to incorporate weight inequalities. The most impressive example is gt2 where just one weight inequality speeds up the solution time enormously. The conclusion we draw from our computational experiences is that in general weight inequalities do not produce significantly worse results (in time and quality). On the other hand, there are examples like $g t 2$ and mitre where weight inequalities help to solve general mixed integer programming problems much faster.
