## Zusammenfassung

Heutzutage gibt es Konferenzen zu fast jeden möglichen Themenbereich. Dabei unterliegt jeder Konferenz ein Veranstaltungsplan, der alle Aktivitäten einer Konferenz räumlich und zeitlich einordnet. Bei wissenschaftlichen Konferenzen bestehen diese Aktivtäten zumeist aus einzelnen Vorträgen, die in sogenannten Sessions zusammengefasst sind. Das Organisationskomitee von diesen Konferenzen ist damit beauftragt, jeder Session eine feste Zeit und einen festen Raum innerhalb der Konferenz zuzuordnen. Dabei soll eine Reihe von komplexen Nebenbedingungen eingehalten werden. Insbesondere bei größeren Konferenzen wird das Zuordnungsproblem dann allgemein sehr schwer überschau- und lösbar.

In dieser Arbeit werden wir die Planungsanforderungen erläutern, die bei größeren Konferenzen entstehen. Weiterhin stellen wir einen Lösungsansatz vor, der Veranstaltungspläne mit Hilfe von mathematischer Optimierung berechnet. Dabei wird das allgemeine Planungsproblem in kleinere Teilprobleme zerlegt, die nacheinander mittels gemischt-ganzzahliger Programmierung modelliert und gelöst werden.

Der Ausgangspunkt unserer Ergebnisse war die Erstellung eines Veranstaltungsplans für das International Symposium on Mathematical Programming 2012 (ISMP) an der $T U$-Berlin. Die ISMP ist einer der größten Konferenzen im Bereich der angewandten Mathematik und Optimierung. Es wurden 1740 Vorträge zu 595 Sessions zusammengefasst, die über eine Woche in 40 parallelen Räumen stattfanden. Das Veranstaltungsprogramm der ISMP 2012 wurde mit Hilfe der hier vorgestellten Modelle erstellt ${ }^{1}$.

[^0]
## 1 Introduction

Scientific conferences play an important role in almost all areas of today's science and research. They offer a wide platform for international researchers and developers for communication and scientific exchange of current problems, experiences and knowledge in nearly all fields of research. Such conferences usually consist of talks about different topics that are given by authorized speakers. The planning process of a conference includes the creation of a scientific program schedule, that means a local and temporal allocation of all available talks.

As the number of talks can grow into thousands for large-scale conferences, the conference scheduling becomes a complex challenge. Furthermore there exist a great bandwidth on various and individual requirements on the allocation of the talks. In this thesis we discuss the major problems that occur during the development of a conference schedule and provide a framework how proper conference schedules can be generated computationally. For that, we use Mixed-Integer-Programming techniques to find schedules that respect the difficult range of additional constraints.

The basis of this thesis was the development of an optimized conference schedule of the International Symposium on Mathematical Programming 2012 (ISMP 2012) in Berlin, Germany. The ISMP is one of the largest conferences in the field of applied mathematics and mathematical optimization and constitutes a great attraction for international mathematicians and researchers. We will present our results based on the problem instance that we used for the ISMP 2012.

## 2 The Conference Scheduling Problem

In the following we will describe the major problems and requirements that arise when scheduling large conferences.

## Combination of talks to sessions

In the beginning, the organizers are mostly confronted with a huge number of submitted talks. At most conferences, each talk must be given within a session. A session includes a couple of talks that are given successively within the session, without any longer breaks in general. At the ISMP 2012, each session consisted of at most three talks, where each talk was limited to 30 minutes speaking time, therefore each session had a total duration of 90 minutes.

The first problem the organizers have to face is to find a suitable aggregation of all submitted talks to sessions. Some sessions may already be formed by the speakers themselves, but a large amount of talks must still be combined in a proper way. It is intended to have talks of similar content in the same session. In addition, sessions that are only partially filled with talks should be avoided, since the attendees of a session should be motivated to attend for the entire session length.

## Session assignment

Once all talks have been assigned to sessions, the next planning step is to create a sci-

Figure 1: Creating sessions
entific program schedule. We assume there are fixed time slots when sessions can take place. Moreover, each time slot is supposed to have a constant duration that is equal to the length of one session. At larger conferences, the number of sessions normally exceeds the number of available time slots, such that sessions have to take place in parallel. Therefore, a minimum number of $\left\lceil\frac{n}{T}\right\rceil$ rooms is needed to allocate all sessions, where $n$ denotes the number of sessions and $T$ the number of time slots. In our considerations the creation of a scientific program schedule solely deals with the allocation of sessions to time slots and rooms. But in addition a huge variety of constraints must be satisfied.

In the following we will look at a typical instance of a conference schedule and describe the related problems by looking at the schedule from different views.

Assume we have given a fixed set of time slots $\{T 1, T 2, \ldots\}$, as well as a set of rooms $\{A, B, \ldots\}$. Furthermore, we suppose that we have given sessions $\{1, \ldots, n\}$. Each session must be assigned to exactly one time and room slot and each time-/room slot can be occupied by at most one session.

| $\mathrm{R} / \mathrm{T}$ | T 1 | T 2 | T 3 | T 4 | T 5 | T 6 |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| room A | 4 | 20 | 9 |  | 21 | 16 |
| room B |  | 6 | 1 | 25 | 23 | 15 |
| room C | 5 | 17 | 2 | 8 | 20 | 3 |
| room D | 7 | 18 | 24 | 19 |  |  |
| room E | 12 | 10 | 13 | 11 | 22 |  |

Figure 2: Session view
The figure shows an exemplary schedule in the session view, where the numbers correspond to a particular session. Such a schedule can be computed quite easily, since it refers to a usual assignment problem. In practice, the amount of additional constraints make this problem more complex.

## Cluster scheduling

Even before the paper submitting phase, the organizers normally offer a set of clusters for the conference. A cluster can be seen as generalized topic that each talk belongs to. We expect that each talk is part of exactly one cluster. The classification of talks to clusters is usually done by the speakers themselves during the abstract submission. Therefore, we assume that this information is given in advance. It is further required that all talks in the same session share the same cluster.

To extend the previous example, we additionally regard a set of clusters $\{1,2 \ldots\}$.

Each session belongs to exactly one of these clusters. The next figure shows the cluster view of the schedule, where the numbers correspond to the cluster of each scheduled session.

| $\mathrm{R} / \mathrm{T}$ | T 1 | T 2 | T 3 | T 4 | T 5 | T 6 |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| room A | 1 | 1 | 1 |  | 1 | 1 |
| room B |  | 4 | 4 | 3 | 3 | 3 |
| room C | 2 | 2 | 6 | 6 | 6 | 6 |
| room D | 5 | 5 | 5 | 5 |  |  |
| room E | 6 | 6 | 6 | 6 | 7 |  |

Figure 3: Cluster view

Obviously, the clusters could have different numbers of sessions. Another requirement on the schedule is that each cluster is supposed to be equally available at each time slot, as hown in the figure. Then, participants will have a higher chance to attend sessions of any cluster of the conference. In addition, it is recommended that the sessions of one cluster take place in the same room. This provides a better orientation and recognition value in an unknown environment for international visitors.

## Room capacity restrictions

Sessions of different clusters will generally deal with different topics, so the interest in these sessions may deviate. There might also be talks that are given by more famous speakers, or talks that present new achievements in some field of research such that there exisits a high general interest in single sessions or talks respectively. Consequently it is obvious that there will occur deviations in the number of attendees of each session. Since every room has a limited number of seats, it is in the responsibility of the organizers to ensure that more attractive sessions will be planned to larger rooms. Overcrowded lecture rooms are one of the major problems, especially at large conferences. For that, we suppose there are constant capacity demands for every session (more on this later). The final schedule has to comply with the room capacities of every assignment. If we extend the previous example, the figure below shows the schedule in the capacity view.

| $\mathrm{R} / \mathrm{T}$ | capacity | T 1 | T 2 | T 3 | T 4 | T 5 | T 6 |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| room A | 200 | 92 | 22 | 75 |  | 53 | 34 |
| room B | 55 |  | 55 | 48 | 12 | 25 | 42 |
| room C | 120 | 70 | 118 | 23 | 90 | 48 | 35 |
| room D | 30 | 29 | 30 | 28 | 25 |  |  |
| room E | 45 | 43 | 26 | 11 | 44 | 33 |  |

Figure 4: Capacity view
The numbers correspond to the capacity demands of every session, or to the number of attendees respectively. Note that the total number of attendees can vary for each time
slot, as not all participants attend for the entire length of the conference. In particular, there are time slots that are attended by more people. From our observations, the peak is usually in the early mid of the conference.

In our approach we focus on the mere compliance with room capacities. That means we do not depreciate, if a small session is scheduled into a proportional larger room.

## Even attractivity distribution

As there are more or less attractive sessions at the conference, it is also not desirable to have too many attractive sessions scheduled in parallel. That is because each time slot should be equally attractive, as well as there must not appear too many attractive sessions at the same time. If we would have given a value of attractivity of each session, then the schedule should respect a roughly even attractivity distribution over all time slots, see the figure below.

Figure 5: Attractivity view
The attractivity view shows the total session attractivity at each time slot. In the best case, the values are equal at each time slot.

## Room distances

Apart from the room capacity, the assignment to rooms includes another difficulty. Whenever a talk has been given within a session, there is a short break of approximately five minutes to answer questions about the content of the talk. Many participants use these breaks for room changes to other talks. Leaving attendees will have to overcome a certain distance to the room of the next talk. As it is hard to estimate which talk each attendee is changing to, we assume that it will be a talk of similar content. For this reason, the distance between similar parallel sessions is supposed to be as small as possible. Of course, this property should hold for all time slots.

The figure below shows an exemplary room map with room changing relations (blue) between similar sessions at some time slot. On the left figure there is shown a proper room assignment, while the right figure illustrates an improper room assignment.

In particular, large-scale conferences include room at several floors and in different buildings, where distances have to be considered. There it is very important that distances are kept short.

Figure 6: Short (left) vs. long (right) room changing distances at some fixed time slot

All in all, these are the main points that must be respected by the final schedule. There are even more constraints, like individual scheduling requests of single sessions. For instance, one speaker is able to attend only the first day of the conference, then it has to be constrained in the schedule. Moreover, some persons have to attend to several sessions at the conference, then it must be ensured that these sessions will not overlap at the same time. More constraints of this type are presented in the upcoming sections.

We conclude that conference scheduling is a very complex issue. A scheduling 'by hand' would be a very time consuming and nearly impossible challenge for large conferences where thousands of different talks and persons are involved. Therefore, mathematical optimization methods find a great application, whenever conference organizers have to deal with the complexity of such problems. In the following, we will present an approach to compute conference schedules that respect the mentioned conditions. As mentioned, the presented optimization models were developed to optimize the ISMP 2012 conference schedule. The problem instance of the ISMP 2012 included 1740 talks which were combined to 595 sessions. These had to be scheduled to five days, each having three time slots for the allocation of sessions. All sessions have been planned, using the minimum number of 40 rooms for parallel sessions. Until now, this was the largest ISMP that has ever taken place.

To provide a better understanding of the underlying combinatorial structures, the optimization models were extended and improved after the ISMP 2012. We will refer to the extended results in this thesis.

### 2.1 Previous Work

The problem of optimizing conference schedules was barely studied in the past. For a closer insight into that problem, we used an existing master thesis [21] that dealt with an equal problem of conference scheduling. For further references, we consulted papers of timetabling models, that mostly dealt with the optimization of university and course
schedules, see [1], [2], [3] and [8]. As our view on the problem is quite specific for itself, we mostly searched for the underlying combinatorial problems, for which we then used further literature.

### 2.2 Notation

We denote the set of talks at the conference by $K$. Each session $s$ can be seen as sequence of successive talks $s=\left(k_{1}, \ldots, k_{m}\right)(m \leq 3$ at ISMP $)$. The set of all sessions is denoted as $S$. Furthermore each session takes place at a certain time slot and in a certain room. The set of all time slots at the conference is given by $T$ and $R$ is the set of available rooms. In addition, each talk and each session belongs to a specific cluster. Then $C$ denotes the set of clusters and we denote the cluster of some talk $k$ by $c_{k}$ and the cluster of some session $s$ by $c_{s}$. Similarly, the sessions that belong to cluster $c$ is defined are given by the set $S_{c}$.

In the upcoming sections, we will present combinatorial problems that have a representation via graphs. We usually define an undirected graph as $G=(V, E)$, where $V$ denotes the set of vertices and $E$ the set of edges between the vertices. We normally denote the set of adjacent vertices of a given vertex $v$ by $\delta(v)=\{u \mid(u, v) \in E\}$. This notation is used for different problems in this thesis. The same holds for the Mixed-Integer-Programs, where the main variables are usually described by $x, y$ and $z$. We emphasize that all models are regarded separately in terms of notation, if not mentioned otherwise. But it should be clear from the context which model is currently used.

## 3 Problem Decomposition

Our first testings revealed quickly that the simultaneous assignment of sessions to timeand room slots is very hard to solve and too time consuming for practical purposes. As the requirements on a large conference schedule are subject to constant changes, we decided that it would be more helpful to use an optimization model that computes solutions in a shorter time span. Therefore, we use a problem decomposition approach, where the entire problem is subdivided into smaller subproblems that are easier and faster to solve. Our decomposition includes the following subproblems:
(1) Combination of Talks to Sessions
(2) Time Assignment
(3) Stream Assignment
(4) Room Assignment

The subproblems are solved successively, where each step uses the solutions of its predecessors. The first optimization step combines all talks to sessions (1) such that similar talks will share the same session. The obtained set of sessions is used for the
further procedure. In the time assignment (2), each session gets assigned to a particular time slot of the conference. It is optimized to evenly distribute the sessions of each cluster over the entire length of the conference. Afterwards, all sessions are arranged to streams in the stream assignment (3). A stream is a sequence of sessions $\left(s_{1}, s_{2}, \ldots, s_{T}\right)$ that successively take place in the same room. It is desired that rooms are occupied by sessions of mainly one cluster for the whole conference. In the last step, each stream is allocated to a particular room in the room assignment (4). The distances between streams, that contain similar sessions, is to be minimized. All subproblems are modeled as Mixed-Integer-Programs. An illustration on the entire optimization process is given in the figure below.

Figure 7: Sequence of optimization models for the conference scheduling problem

## 4 Combining Talks to Sessions

After the paper-submission phase, the conference organizers have to combine the submitted talks to sessions. The problem is to find a suitable combination of talks to sessions, where talks with overlapping content should be given within the same session. In particular, only talks of the same cluster will be combined. Furthermore sessions are supposed to be completely filled with talks, since partially filled sessions are rather unattractive to attend.

In the following we present two Mixed-Integer-Programming approaches that make use of different combinatorial problems. Both approaches yield an aggregation of all talks to sessions. The total similarity between talks in one session is maximized, as well as the total idle time in the created sessions is minimized. From our point of view, the first model yields a better representation of the actual problem, but is more difficult to solve. On the contrary, the second model is much easier to solve but just partially reflects the underlying problem. In addition, the needed problem data is more difficult to obtain and to characterize.

We have to mention, that the models of this section have not been used for the ISMP 2012. But in retrospect, they find a great application, when the conference planning is considered as a whole. For this reason, our computational experience was made with randomized data.

In the following we will consider the generalized case, where talks may have arbitrary lengths. Therefore, we denote the constant duration of all sessions by $D$ and the length of talk $k$ by $d_{k}$. In particular, for the ISMP instance it holds $d_{k}=30$ for all $k \in K$ and $D=90$ (in minutes), what we could also simplify to $D=3$ and $d_{k}=1$ for all $k \in K$.

### 4.1 Clique Partitioning approach

For this problem we have given an undirected graph where each talk $k \in K$ represents a vertex. Every talk is supposed to have a similarity relation to all other talks of the same cluster $c \in C$. These relations are modeled as undirected edges from an edge set $E=\left\{(k, l) \mid k, l \in K, k<l, c_{k}=c_{l}\right\}$. Every edge $(k, l)$ has an edge weight $\sigma_{k l} \in \mathbb{R}$ that defines the similarity between talks $k$ and $l$. Its value indicates the overlap in the content of the talks. The higher the value of $\sigma_{k l}$ the higher is the overlap. The induced graph is given by $G=(K, E)$.

All talks within the same session have a similarity relation to each other. Hence, we will regard each session as complete subgraph of $G$, a clique. The problem is to find a partition of $K$ into disjoint subsets $K_{1}, \ldots, K_{m}$, such that for all $i \in\{1, \ldots, m\}$ each $K_{i}$ induces a session or a clique respectively. We define the size of a clique, as the number of vertices in the inuduced subgraph. The total similarity of the sessions, that is the total edge weight of all cliques, is to be maximized. This combinatorial problem is also known as the Clique Partitioning Problem (CPP) that was shown to be $\mathcal{N} \mathcal{P}$-hard. It has been studied by Grötschel and Wakabayashi [4][22] who introduced different cutting plane techniques for this problem. Ji and Mitchell [23] considered the problem with minimum clique size requirement and propose a branch-and-cut algorithm.

Our considerations include further restrictions concerning the length of the sessions and talks. For every session $K_{i}$ the sum of the lengths of all talks in $K_{i}$ must not exceed the duration of the session, that is $\sum_{k \in K_{i}} d_{k} \leq D$. Thus, $d_{k}$ can be seen as additional vertex weight, where each clique bounds the weight of all contained vertices by $D$. These knapsack conditions within a clique partitioning problem has been studied by Mehrotra and Trick [24].

Furthermore, our model penalizes the unused capacity of each clique, as this corresponds to the idle time in each session which is to be minimized. In addition, we have another requirement on the maximum number of cliques in the clique partitioning, since the number of sessions is bounded by the number of available time- and room slots.

Figure 8: Three possible sessions (cliques) with duration of $D=90$ that contain talks of length $d_{k}=30$ and the induced idle time

In the following we will present an integrated Mixed-Integer-Program that solves the problem with respect to the mentioned constraints.

## Mixed Integer Program

For every edge $(k, l) \in E$ we introduce binary variables $x_{k l}$, that take on the value 1 , if talks $k$ and $l$ appear in the same session. The number of possible sessions is bounded by the number of available assignment slots, that is $|T| \cdot|R|$. Consequently, the number of cliques in the graph must be restricted to this amount. From the modeling view, restricting the number of cliques is a non-trivial matter, so we introduce further variables. Let $W=\left\lceil\frac{D}{\min _{k \in K} d_{k}}\right\rceil$, then $B=\{1, \ldots, W\}$ denotes the set of possible clique sizes. Furthermore, let $z_{k b}$ denote the binary variable which takes on the value 1 , if talk $k$ is contained in a session of size $b \in B$, and 0 otherwise. Moreover, let $y_{k b} \geq 0$ denote the amount of idle time that is induced by talk $k$, if it is contained in a session of size $b$. A more detailed explanation on this variable is given later. At large conferences, it is usual that sessions can also be created by the speakers themselves. Therefore let $K_{+}$ denote the set of talk pairs of the same cluster, which are supposed to appear in the same session. The Mixed Integer Program reads as follows:

$$
\begin{array}{lll}
\max & \lambda \sum_{(k, l) \in E} \sigma_{k l} x_{k l}-(1-\lambda) \sum_{k \in K} \sum_{b \in B} y_{k b} \\
& & \\
\text { s.t. } & x_{j k}+x_{k l}-x_{j l} \leq 1 & \\
& x_{j k}-x_{k l}+x_{j l} \leq 1 & \\
& -x_{j k}+x_{k l}+x_{j l} \leq 1 & \\
& \sum_{b \in B} z_{k b}=1 & \forall k \in K),(k, l),(j, l) \in E \\
& y_{k b} \leq D \cdot z_{k b} & \forall k \in K, b \in B \\
& \sum_{l \in \delta(k)} x_{k l}=\sum_{b \in B}(b-1) \cdot z_{k b} & \forall k \in K \\
& d_{k}+\sum_{l \in \delta(k)} d_{l} x_{k l}+\sum_{b \in B} b \cdot y_{k b}=D & \forall k \in K \\
&  \tag{7}\\
\sum_{k \in K} \sum_{b \in B} \frac{1}{b} z_{k b} \leq|T| \cdot|R| & & \\
x_{k l}=1 & \forall(k, l) \in K_{+} \\
x_{k l} \in\{0,1\} & \forall(k, l) \in E \\
y_{k b} \geq 0 & \forall k \in K, b \in B \\
z_{k b} \in\{0,1\} & \forall k \in K, b \in B
\end{array}
$$

The similarities between talks in the same sessions are maximized in the objective function, as well as the total idle time in all sessions is minimized. The coefficient $\lambda \in[0,1]$ weights the importance between the two objectives. Constraints (1) are the triangle inequalities, which indicate that whenever two edges in a triangle ( $j, k, l$ ) are selected, then also the third edge must be selected. Together with the integrality condition $x_{k l} \in\{0,1\}$ for all $(k, l) \in E$, the integral points that satisfy these inequalities yield a complete description of all clique partitionings in $G$, see [4]. Inequalities (2) say that each talk must be assigned to a session of a particular size. If some talk $k$ is not contained in a session of size $b$, then it induces no idle time $y_{k b}$ there (3). Constraints (4) state that the number of adjacent edges of some talk $k$ is exactly the size of the clique of $k$ minus one. Further, the sum of the lengths of all talks in a session must not exceed the maximal duration $D$ of a session, what is modeled by (5). The term $\sum_{b \in B} b \cdot y_{k b}$ is used to count the correct amount of idle time in the objective function, because every clique member shares the idle time. Inequality (6) says that the number of sessions must not exceed the maximum number of sessions, what is $|T| \cdot|R|$. In addition $x_{k l}$ must be fixed to one for all $(k, l) \in K_{+}(7)$.

## Reduction of the problem size

In practical implementation, the triangle inequalities (1) have a huge impact on the complexity of this problem, as the number of constraints grows rapidly, even for smaller instances. Therefore, it was hard to find proper solutions for our problem instances. For this reason, we did a reduction approach to reduce the number of constraints to a manageable amount. Our approach was to eliminate 'redundant' edges. In our model we regard an edge as redundant, if it does not satisfy a certain value $\sigma$ of similarity. More precise, all edges $(k, l) \in E$ with $\sigma_{k l}<\sigma$ are eliminated. This seems useful, as edges with a lower similarity value are rather unattractive to choose. Therefore, we define the reduced edge set as $E^{\prime}=\left\{(k, l) \in E \mid \sigma_{k l} \geq \sigma\right\} \subseteq E$ and apply the model to the sparse graph $G^{\prime}=\left(K, E^{\prime}\right)$. With this reduction approach, the completeness property of the subgraphs is lost in general due to the elimination, so the triangle inequalities do not give a full representation of the clique partitionings in $G^{\prime}$ anymore. Thus, we have to replace the triangle inequalities (1) by the following set of constraints to regain a full description.

$$
\begin{array}{lll}
x_{j k}+x_{k l}-x_{j l} \leq 1 & \forall(j, k),(k, l),(j, l) \in E^{\prime} \\
x_{j k}-x_{k l}+x_{j l} \leq 1 & \forall(j, k),(k, l),(j, l) \in E^{\prime} \\
-x_{j k}+x_{k l}+x_{j l} \leq 1 & \forall(j, k),(k, l),(j, l) \in E^{\prime} \\
& \forall(j, k),(k, l) \in E^{\prime}:(j, l) \notin E^{\prime}, j<l \\
x_{j k}+x_{k l} \leq 1 & \forall(j, k),(j, l) \in E^{\prime}:(k, l) \notin E^{\prime}, k<l \\
x_{j k}+x_{j l} \leq 1 & \left.\forall(k, l),(j, l) \in E^{\prime}:(j, k) \notin E^{\prime}\right), j<k \\
x_{k l}+x_{j l} \leq 1 &
\end{array}
$$

Inequalities (1') are the triangle inequalities, as used before for each triangle in the sparse graph. If one edge of an arbitrary triangle in $G$ is lost due to the elimination, we have to ensure that at most one of the two remaining edges belongs to a clique of the clique partitioning of $G^{\prime}\left(1^{\prime \prime}\right)$. An equivalent interpretation of these inequalities is to set $x_{k l}=0$ in (1) for all eliminated edges $(k, l) \notin E^{\prime}$, where ( $1^{\prime}$ ) and ( $1^{\prime \prime}$ ) are the usual triangle inequalities. The benefit arises from the fact that triangles with two deleted edges induce a redundant triangle inequality.

## Computational experience

Since this problem is $\mathcal{N} \mathcal{P}$-hard, it was not surprising that the problem was not solvable with the general formulation. Therefore, we introduced the elimination approach, in order to reduce the huge number of triangle inequalities in the model. This made it possible for us to compute solutions for problem sizes of the ISMP, or even larger. But in general, we can be far from the optimum, so we considered another formulation that is presented in the next section.

### 4.2 Capacitated Facility Location approach

The main idea of this model approach is to assign each talk $k \in K$ to a session $s \in \bar{S}$ of a preformed session set $\bar{S}$. Whenever a talk is assigned to a session, then this session
is 'opened'. Here it is important that each session of $\bar{S}$ already belongs to a certain cluster $c \in C$ such that talks are only assigned to sessions of equal cluster. It also ensures that talks of different clusters are not assigned to the same session. Therefore let $\bar{S}_{k}=\left\{s \in S \mid c_{s}=c_{k}\right\}$ for all $k \in K$ and $K_{s}=\left\{k \in K \mid c_{s}=c_{k}\right\}$ for all $s \in \bar{S}$. Furthermore, each assignment $(k, s)$ of talk $k$ to session $s$ has a similarity value $\sigma_{k s}$ that indicates the similarity of talk $k$ to session $s$. The first objective is to maximize the total similarity of the talks to the sessions, while each talk must be assigned to a particular session. Secondly, the occurring idle time of each session should be minimized. In order to respect the maximum possbile number of sessions, we have to bound the total number of opened sessions by $|T| \cdot|R|$. As in the previous model, it must be ensured that the total length of all assigned talks does not exceed the duration limit $D$ of each session. In the end, each opened session $s \in \bar{S}$ forms a 'real' session at the conference that contains all assigned talks.

In combinatorial optimization, this problem variant is better known as $n$-Single Source Capacity Location Problem ( $n$-SSCFLP). There we have given a set of customers and a set of potential facility locations, where each customer must be assigned to exactly one opened facility. The total assignment cost and the total opening cost of all facilities should be minimized. Moreover, the capacity of each facility must be sufficient to serve the demand of all assigned customers. Also, the number of opened facilities is bounded by a constant $n$. The n-SSFCLP belongs to the class of $\mathcal{N} \mathcal{P}$-hard problems.

If we transform our problem to the n-SSCFLP, each talk $k$ corresponds to a customer that has demand $d_{k}$, as well as each session $s$ is associated with a potential facility that has capacity $D$ and opening cost equal to zero. The assignment cost is given by $-\sigma_{k s}$, thus $\sigma_{k s}$ is the profit to assign customer $k$ to facility $s$. The bound on the maximum number of openend facilites is $n=|T| \cdot|R|$ in our case.

In contrast to the general formulation of the n -SSCFLP, we also want to minimize the idle time in each session, what can be seen as additional cost for 'unused capacity' of each facility. Additionally, there are talk pairs which have to be scheduled within the same session. We will see that these conditions can be implemented with a common n-SSCFLP formulation. The figure below shows an illustration to this modeling variant.

Figure 9: Different assignments of talks with length $d_{k}=30$ to sessions with duration of $D=90$ and the induced idle time (unused capacity)

## Mixed Integer Program

For every assignment $(k, s)$ of talk $k$ to session $s$, there is the binary variable $x_{k s}$ which takes on the value 1 , if talk $k$ is assigned to session $s$, and 0 otherwise. The variable $y_{s} \geq 0$ denotes the amount of idle time in each session $s$. Furthermore, the decision variable $z_{s}$ is 1 , if session $s$ is opened, and 0 otherwise. Equally to the previous model, $K_{+}$denotes the set of talk pairs, that should be allocated to the same session. Especially it must hold $c_{k}=c_{l}$ for all $(k, l) \in K_{+}$. The Mixed-Integer-Program states as follows:

$$
\begin{array}{ll}
\max & \lambda \sum_{(k, s) \in E} \sigma_{k s} x_{k s}-(1-\lambda) \sum_{s \in \bar{S}} y_{s} \\
\text { s.t. } & \sum_{s \in \bar{S}_{k}} x_{k s}=1
\end{array} \quad \forall k \in K
$$

The objective function maximizes the total similarity of the assignments of talks to sessions, as well as the total idle time in the created sessions is minimized. The coefficient $\lambda \in[0,1]$ weights the importance between the two objectives. Constraints (1) ensure that every talk is assigned to exactly one session. Inequalities (2) express that the talk lengths may not exceed the duration of each session and its gap is exactly the idle time of the session. Inequalities (3) are not necessary for the formulation, but they yield stronger bounds for linear relaxation of the problem. In (4), the total number of opened sessions must not exceed the number of available session slots, that is $|T| \cdot|R|$. Constraint (5) guarantees, that all talks in $K_{+}$are assigned to the same session.

If we take a closer look to the model, we see that it can be transformed to a common n-SSCFLP. For that, we rearrange inequality (2) and see that we can get rid of the $y_{s}$ variables:

$$
\begin{equation*}
0 \leq y_{s}=D \cdot z_{s}-\sum_{k \in K} d_{k} \cdot x_{k s} \tag{2}
\end{equation*}
$$

$$
\sum_{k \in K} d_{k} \cdot x_{k s} \leq D \cdot z_{s} \quad \forall s \in \bar{S}
$$

Constraints (2) are replaced by (2') which now correspond to the ususal capacity requirement of an $n-S S C F L P$. The definition of $y_{s}$ in $(2)$ is then inserted into the objective function:

$$
\begin{aligned}
& \max \sum_{(k, s) \in E}\left(\lambda \sigma_{k s}+(1-\lambda) d_{k}\right) x_{k s}-\sum_{s \in \bar{S}}(1-\lambda) D \cdot z_{s} \\
& =\max \underbrace{\sum_{k \in k}(1-\lambda) d_{k}}_{\text {const. }}+\sum_{(k, s) \in E} \lambda \sigma_{k s} x_{k s}-\sum_{s \in \bar{S}}(1-\lambda) D \cdot z_{s} \\
& \Leftrightarrow \min \sum_{(k, s) \in E} \sigma_{k s}^{\prime} x_{k s}+\sum_{s \in \bar{S}} f_{s} z_{s}
\end{aligned}
$$

Now, inequalities (1) - (4) correspond directly to the n-SSCFLP formulation with new assignment cost $\sigma_{k s}^{\prime}=-\lambda \sigma_{k s}$ and facility opening cost $f_{s}=(1-\lambda) D$. This has the natural interpretation that the idle time just depends on the number of opened sessions, while the total duration of the talks is constant anyway.

Constraints (5), which expressed that talk pairs $(k, l) \in K_{+}$must be assigned to the same session, can also be eliminated by replacing all talks, that must be scheduled into one session, by a new greater talk that has the total duration of all replaced talks.

## Computational experience

For our computational results we choose $\bar{S}=K$, that means it is possible to open a session for each talk. As the similarities occur between talks, we used the same similarities, as in the clique partitioning model. In contrast to the previous approach, this problem is properly solvable without reducing the problem size. But in contrast to the CPP, it does not yield a proper formulation of the underlying problem, as some similarity relations (between the customers) are not considered. Therefore it gives just a partial representation of the actual problem.

## 5 Time Assignment

In this section we will present the next optimization step, the time assignment. It yields an assignment of all sessions to time slots. The entire time assignment model includes a huge variety of different constraints. For this reason, we will present a general Mixed-Integer-Programming formulation first, until further classes of constraints are introduced. Based on that, we will give an approach to the robust optimization of the schedule, that relates to the uncertain number of attendees of every session and the compliance with room capacities.

### 5.1 Mathematical Optimization Model

In the optimization model, each session $s \in S$ is assigned to a time slot $t \in T$. This is modeled by decision variables $x_{s t}$, with:

$$
x_{s t}= \begin{cases}1, & \text { if session } s \text { takes place at time slot } t \\ 0, & \text { otherwise }\end{cases}
$$

A solution of the time assignment model yields a partition of $S$ into disjoint sets $S_{1}, \ldots, S_{T}$ with $S_{t} \cap S_{t^{\prime}}=\emptyset$ for all pairwise distinct $t, t^{\prime} \in T$. In that sense, $S_{t}$ contains all sessions that are scheduled at time slot $t$. These sets are used as input for the upcoming optimization models. In the next sections we present a comprehensive description of the core-model, which is followed by further classes of constraints.

### 5.1.1 Core model - Modeling an evenly distributed schedule

Each conference participant has individual preferences concerning the choice of his session. But it is natural to assume that every participant focuses only on a selection of topics that he is interested in. These topics are generalized given by the set of clusters $C$. As each session belongs to exactly one cluster $c$, the sessions of a cluster are supposed to be equally available at every time slot of the conference.
That means for every cluster $c \in C$ the set $S_{c} \subseteq S$, what is the set of sessions that belongs to $c$, must be evenly distributed over all $t \in T$. For a given cluster $c$ the following illustration shows how $S_{c}$ should be distributed over the time slots in the best case.

Figure 10: Exemplary time assignment for $S_{c}$
The figure shows the distribution of $S_{c}$ over an exemplary conference with time slots $T=\{T 1, \ldots, T 9\}$. This example shows the best distribution for $S_{c}$, in a sense, that will be explained during the further procedure. We see that $S_{c}$ is evenly distributed over all time slots, so participants, who are interested in cluster $c$, are able to attend the sessions of $c$ at every time slot. Each day of the conference has exactly three time slots. At day 1 and day 3 there occur three parallel sessions of $S_{c}$, while at day 2 there are scheduled two parallel sessions. Time slots with a maximum number of sessions should appear together at entire days (day 1 and day 3 ). This is desired, because 'cluster gaps' should be avoided during a single day, that means one room is supposed to be occupied
by sessions of one cluster for the whole day. We also want that $S_{c}$ can be scheduled in the minimum possible number of rooms. With this time distribution, it it possible that $S_{c}$ occupies the minimum number of three rooms.

In the following we present a Mixed-Integer-Program to obtain such an evenly distributed schedule for arbitrary subsets of sessions $S^{\prime} \subseteq S$. For that, we need to introduce further definitions and properties of the schedule.

Let $b_{t}$ denote the number of sessions of a fixed cluster at time slot $t$. Assume that a participant is interested in this specific cluster only, that means he will attend sessions of this cluster only. Additionally, we have to assume that he is able to attend only one session at each time slot. Let $\omega$ denote the number of different session programs $s_{1}, \ldots, s_{T}$ that our participant can choose for the whole conference.

Claim 1. $\omega$ is maximal if and only if $\left|b_{t}-b_{t^{\prime}}\right| \leq 1$ for all pairs of time slots $t, t^{\prime} \in T$.
Proof. As it is possible to choose only one session per time slot, the number different session programs is the product over the number of available sessions at each time slot, except those with $b_{t}=0$. Let $T^{\prime}$ be the set of time slots $t$ with $b_{t}>0$, then he can choose $\omega=\prod_{t \in T^{\prime}} b_{t}$ different session programs for the conference.

Let $\omega$ be maximal and assume that $b_{t}-b_{t^{\prime}}>1$ for two different time slots $t, t^{\prime} \in T$. Swapping one session from $t$ to $t^{\prime}$ yields:

$$
\left(b_{t}-1\right)\left(b_{t^{\prime}}+1\right) \prod_{t \in T^{\prime} \backslash\left\{t, t^{\prime}\right\}} b_{t}=\left(b_{t} b_{t^{\prime}}+b_{t}-b_{t^{\prime}}-1\right) \prod_{t \in T^{\prime} \backslash\left\{t, t^{\prime}\right\}} b_{t}>b_{t} b_{t^{\prime}} \prod_{t \in T^{\prime} \backslash\left\{t, t^{\prime}\right\}} b_{t}=\omega
$$

This forms a contradiction on $\omega$ being maximal.
To show the other direction, let $\left|b_{t}-b_{t^{\prime}}\right| \leq 1$ for all $t, t^{\prime} \in T^{\prime}$ and assume that $\omega$ is not maximal. Any deviation of the distribution that preserves $\left|b_{t}-b_{t^{\prime}}\right| \leq 1$ yields the same $\omega$. Consequently in a distribution, where $\omega$ is maximal, it must hold $b_{t}-b_{t^{\prime}}>1$ for two time slots $t$ and $t^{\prime}$. But then we could always find a greater $\omega$, equally to the case before. This contradicts to the fact that $\omega$ is maximal in such a distribution.

Since we expect many participants to concentrate on a few clusters only, the claim yields a nice property for the schedule. There, the number of different session programs for one cluster is maxed out.

The next definitions are needed to define an evenly distributed schedule, as shown in Figure 10.

Definition 2. Let $S^{\prime} \subseteq S$ be an arbitrary subset of sessions. We call a time slot $t$ maximal for $S^{\prime}$, if $b_{t^{\prime}} \leq b_{t}$ for all $t^{\prime} \in T$.

Definition 3. Let $D$ denote the set of days for the conference. We define $T_{d}$ as the set of time slots, which belong to day $d \in D$. We say a set of sessions $S^{\prime} \subseteq S$ is bundled at day $d$, if all time slots $t \in T_{d}$ are maximal for $S^{\prime}$.

Definition 4. We say a set of sessions $S^{\prime} \subseteq S$ has an evenly distributed schedule (EDS), if the following properties hold:
(i) $\left|b_{t}-b_{t^{\prime}}\right| \leq 1$ forall $t, t^{\prime} \in T$
(ii) the number of bundled days is maximal, with respect to (i)

The time assignment of $S_{c}$ in Figure 10 has an EDS, because two time slots differ by at most one session (i), and the number of bundled days (day 1 and 3 ) is maximal (ii). In our considerations it is not important which days are bundled, as long as the number of bundled days is maximal.

Next, we introduce a Mixed-Integer-Programming approach, that models an EDS for arbitrary session sets $S^{\prime} \subseteq S$. For that, we define $\mathcal{S}$ as the set of session-subsets, for which an EDS should be applied. Since every cluster is supposed to be evenly distributed we define $\mathcal{S}=\bigcup_{c \in C}\left\{S_{c}\right\}$, that means the elements of $\mathcal{S}$ are the session sets of each cluster. For simplicity in the further notation we use the index set $J$ to denote all EDS sets with $\mathcal{S}=\bigcup_{j \in J}\left\{S_{j}\right\}$. This will be helpful to describe further EDS sets that are introduced later.

## Mixed Integer Program

For each $j \in J$ we define the variable $U_{j} \geq 0$ that is an upper bound on the number of sessions of $S_{j} \in \mathcal{S}$ at all time slots. Furthermore let $y_{j t}$ be a binary variable which takes on the value 1 , if time slot $t$ is maximal for $S_{j}$, and 0 otherwise. The binary variable $z_{j d}$ is equal to 1 , if $S_{j}$ is bundled at day $d$, and 0 otherwise. The following Mixed-Integer-Program produces an assignment of each session to a time slot, such that each $S_{j}$ receives an EDS. Therefore $\lambda_{1}, \lambda_{2}, \lambda_{3}>0$ are weight coefficients, that are specified later.

$$
\begin{array}{lll}
\min & \lambda_{1} \sum_{j \in J} U_{j}+\lambda_{2} \sum_{j \in J} \sum_{t \in T} y_{j t}-\lambda_{3} \sum_{j \in J} \sum_{d \in D} z_{j d} \\
\text { s.t. } & \sum_{t \in T} x_{s t}=1 & \forall s \in S \\
& U_{j}+y_{j t}-\sum_{s \in S_{j}} x_{s t} \geq 1 & \forall j \in J, t \in T \\
& \sum_{t \in T} y_{j t} \geq 1 & \forall j \in J \\
& &  \tag{4}\\
& & \\
& & \\
& x_{s d} \in j \in J, y_{j t} \leq 0 & \\
U_{j} \geq 0 & \forall j \in S, t \in D \\
y_{j t} \in\{0,1\} & \forall j \in J, t \in T \\
z_{j d} \in\{0,1\} & \forall j \in J, d \in D
\end{array}
$$

The objective function minimizes $U_{j}$, what is the maximal number of sessions that are scheduled at some time slot. In addition, the number of maximal time slots is minimized and the number of bundled days is maximized for every $S_{j} \in \mathcal{S}$. Inequalities (1) mean, that every session must be assigned to exactly one time slot. Constraints (2) indicate, that $U_{j}$ is bounded from below by the number of sessions at time slot $t$, if $t$ is maximal for $S_{j}\left(y_{j t}=1\right)$. Otherwise, if $t$ is not maximal for $S_{j}\left(y_{j t}=0\right)$, then $U_{j}$ must differ by at least one from the number of sessions at $t$. This is because at least one maximal time slot must exist for every $S_{j}(3)$. Inequalities (4) say, that if $S_{j}$ is bundled at day $d$, then all $t \in T_{d}$ must be maximal.

Note that $U_{j}$ is always integral in an optimal solution of the model. Moreover, the integrality condition of $z_{j d}$ can be relaxed to $0 \leq z_{j d} \leq 1$.

The next figure illustrates the relation between an arbitrary time assignment and the induced variables values.

Figure 11: Time assignment and the induced variable values and for session set $S_{j}=S_{c}$

Remark. In particular, an optimal solution of the optimization model yields an EDS for every $S_{j}$, only if the weight coefficients $\lambda_{1}, \lambda_{2}, \lambda_{3}$ are chosen correctly. Therefore we have to make a distinction between the variables in the objective function to obtain an EDS for every $S_{j}$ with $j \in J$.

Proposition 5. Let $\lambda_{1}>(|T|-1) \cdot \lambda_{2}$ and $\lambda_{2}>\lambda_{3}$. A solution of the above time assignment model is optimal with respect to weight coefficients $\lambda_{1}, \lambda_{2}, \lambda_{3}>0$, if and only if all $S_{j} \in \mathcal{S}$ with $j \in J$ have an evenly distributed schedule (EDS).

Proof. Let $x=\left(x_{s t}\right)_{s \in S, t \in T}$ be the assignment vector of an optimal solution of the timeassignment with $\lambda_{1}>(|T|-1) \cdot \lambda_{2}$ and $\lambda_{2}>\lambda_{3}$. For the proof we look at an arbitrary session set $S_{j}$ and assume that it has no evenly distributed schedule. Therefore, there must either exist time slots $t, t^{\prime}$ with $\sum_{s \in S_{j}} x_{s t}-\sum_{s \in S_{j}} x_{s t^{\prime}}>1$ or the number of time slots is not maximal, when $\sum_{s \in S_{j}} x_{s t}-\sum_{s \in S_{j}} x_{s t^{\prime}} \leq 1$.

At first, we will consider the case of $\sum_{s \in S_{j}} x_{s t}-\sum_{s \in S_{j}} x_{s t^{\prime}}>1$ for time slots $t, t^{\prime} \in T$ and make a case-by-case-analysis. W.l.o.g we can assume that $t$ is a maximal time slot.

Case 1: $t$ is the only maximal time slot.
Swapping a session from time slot $t$ to $t^{\prime}$ decreases $U_{j}$ by one, because $U_{j}$ was bounded from below by the number of sessions at a maximal time slot. As $t$ was the only maximal time slot, $U_{j}$ can be decreased by one due to this swap. The number of maximal time slots could increase to at most $|T|-1$, since there exists at least one maximal time slot in any time assignment. However, the number of bundled days can only be increased due to the swap, so we obtain a cost reduction of $-\lambda_{1}+(|T|-1) \cdot \lambda_{2}<0$ in the worst case. But that is a contradiction on $x$ being optimal.

Case 2: $t$ is not the only maximal time slot.
Swapping one session from $t$ to $t^{\prime}$ decreases the number of maximal time slots by one. Since there is at least one further maximal time slot, $U_{j}$ could not be decreased and remains the same. However, at most one bundled day could be destroyed due to the swap. Then we would obtain a cost reduction of $-\lambda_{2}-\left(-\lambda_{3}\right)<0$, what is a contradiction on $x$ being optimal.

Consequently, if $x$ is optimal, then it holds $\left|\sum_{s \in S_{j}} x_{s t}-\sum_{s \in S_{j}} x_{s t^{\prime}}\right| \leq 1$ for all $t, t^{\prime} \in T$. If this property holds, then also the number of bundled days is maximal, because it is maximized in the objective function.

For the other direction we require all $S_{j}$ with $j \in J$ to have an EDS, that is given by the assignment vector $x=\left(x_{s t}\right)_{s \in S, t \in T}$ and the variables $U, y, z$. We assume, that $x$ is not optimal for the objective function $\min \sum_{j \in J}\left(\lambda_{1} U_{j}+\lambda_{2} \sum_{t \in T} y_{j t}-\lambda_{3} \sum_{d \in D} z_{j d}\right)$. Thus, there must exist at least one $j \in J$, for which the sub-objective function $\min \lambda_{1} U_{j}+$ $\lambda_{2} \sum_{t \in T} y_{j t}-\lambda_{3} \sum_{d \in D} z_{j d}$ has strictly higher cost than in the optimal solution. Let $x^{*}, U^{*}, y^{*}, z^{*}$ be the variables values of an optimal time assignment. Again, we do a proof by cases. As already mentioned, one of the following cases must occur for some $j \in J$ :

Case 1: $U_{j}^{*}<U_{j}$
In an EDS, $U_{j}$ is already minimal, so $U_{j}^{*}$ cannot be smaller, as it is bounded from below by the same amount of sessions.

Case 2: $\sum_{t \in T} y_{j t}^{*}<\sum_{t \in T} y_{j t}$
Any EDS-preserving deviation of the schedule yields the same amount of maximal time slots. Therefore, the only possibility to decrease $\sum_{t \in T} y_{j t}$, is to swap a session to an existing maximal time slot $t^{\prime}$. Then, $t^{\prime}$ would form the only maximal time slot and the amount of maximal time slots would particularly be minimal $(=1)$. As $U_{j}$ is bounded from below by the number of sessions at any time slot, $U_{j}$ is increased by one due to this swap. For such a deviation, the largest possible difference in the number of maximal time slots ranges from $|T|$ to 1 in the best case. Then the cost changes to $\lambda_{1}-(|T|-1) \lambda_{2}>0$.

Case 3: $\sum_{d \in D} z_{j d}<\sum_{d \in D} z_{j d}^{*}$
If we increase the number of bundled days, then also the number of maximal time slots must be increased by at least one. This yields the cost change of $\lambda_{2}-\lambda_{3}>0$.

Finally we can exclude case 1 . For case 2 and 3 it is not possible to decrease the number of maximal time slots or to increase the number of bundled days respectively, without increasing the cost. Finally, there exists no $j \in J$, for which the optimal solution
has strictly smaller cost, that means $x$ must be optimal. This contradicts the assumption.

Proposition 5 holds for both directions, consequently no evenly distributed schedule is excluded with the Mixed-Integer-Program formulation. With respect to that, we apply the following weight coefficients to the objective function:

$$
\min \quad 2|T| \sum_{j \in J} U_{j}+2 \sum_{j \in J} \sum_{t \in T} y_{j t}-\sum_{j \in J} \sum_{d \in D} z_{j d}
$$

### 5.1.2 Room capacity restrictions

Each session differs in its cluster, content, speakers and the contained talks. Naturally, each attendee has own interests and preferences concerning the choice of his session. Hence, all sessions will obviously have different numbers of attendees. As each session takes place in a certain room, it is necessary that the available number of seats is not exceeded. Especially for large conferences, where the room sizes may be significantly different, the compliance with room capacities is a very important requirement on the schedule.

In this section we will refer to the work of Lübbecke and Lach [2][3]. They present inequalities that satisfy room capacity restrictions within a time assignment. This is a non-trivial matter, as we are just considering assignments of sessions to time slots in this model. We further want give a proof that these inequalities are sufficient to model the compliance with room capacities in a time assignment.

In the following let $u_{r}$ denote the capacity of a room $r \in R$ and let $a_{s}$ indicate the number of attendees in a session $s \in S$. A more detailed study on how $a_{s}$ is determined, is given in Section 5.2, but we naturally assume that $a_{s}>0$.

Definition 6. An assignment $(s, r)$ of a session $s$ to room $r$ is called feasible, if the number of attendees does not exceed the capacity, that means $a_{s} \leq u_{r}$.

Let $S_{t}$ be the set of all sessions, that are scheduled at time slot $t$. This set is actually not defined yet, because it is only given by a solution of the time assignment. But in the following we will give sufficient conditions for $S_{t}$ to comply with the room capacities. These conditions can be formulated by means of linear inequalities, as proposed in [2] and [3]. For that, we model each session $s \in S_{t}$ and every room $r \in R$ as vertices in the vertex set $S_{t} \cup R$. Furthermore let $E$ be a set of the undirected edges, that model all feasible assignments ( $s, r$ ) between sessions $s \in S_{t}$ and rooms $r \in R$. We define $G_{t}=\left(S_{t} \cup R, E\right)$ as the feasible assignment graph for time slot $t$. In particular, $G_{t}$ is a bipartite graph with the bipartition $\left\{S_{t}, R\right\}$.

Definition 7. Let $G=(V, E)$ be an undirected graph. $\mathcal{M} \subseteq E$ is called a matching of $G$, if the edges of $\mathcal{M}$ have no vertex in common. $\mathcal{M}$ is a perfect matching, if every vertex $v \in V$ is incident to an edge in $\mathcal{M}$.

Lemma 8. The sessions of $S_{t}$ comply with the capacities of $R$ if and only if the feasible assignment graph $G_{t}$ contains a matching $\mathcal{M}$ such that each vertex of $S_{t}$ is incident to an edge in $\mathcal{M}$.

Proof. Let $S_{t}=\left\{s_{1}, \ldots, s_{m}\right\}$, then $S_{t}$ complies with room capacities if there are feasible assignments $\left(s_{1}, r_{1}\right), \ldots,\left(s_{m}, r_{m}\right)$ for all sessions of $S_{t}$ to distinct rooms $r_{i} \neq r_{j}$ for all $i, j \in\{1, \ldots, m\}$ with $i \neq j$. These feasible assignments directly correspond to the edges of the matching $\mathcal{M}$. The other direction is analogous.

Consequently, our optimization model must ensure, that there exists such a matching for all $G_{t}$ with $t \in T$. As proposed in [2] and [3], we refer to the theorem of Hall, that yields a sufficient condition on the existence of such a matching.

Hall's Matching Theorem. Let $G=(V, E)$ be an undirected bipartite graph with the bipartition $V=A \cup B$ and the edge set $E$. Let $\Gamma(A) \subseteq B$ be the set of vertices that are adjacent to vertices in $A$. G contains a perfect matching if and only if $\left|A^{\prime}\right| \leq\left|\Gamma\left(A^{\prime}\right)\right|$ for all $A^{\prime} \subseteq A$.

We will apply this theorem to our feasible assignment graph $G_{t}$ with $A=S_{t}$ and $B=R$. Note that the theorem also works for $\left|S_{t}\right| \leq|R|$, as the number of sessions at some time slot may be smaller than the number of rooms. Let $S^{\prime} \subseteq S$ be an arbitrary subset of sessions and let $\Gamma\left(S^{\prime}\right) \subseteq R$ be the set of rooms that are adjacent to sessions of $S^{\prime}$ in $G_{t}$. The cardinality of $S^{\prime} \cap S_{t}$ is given by $\sum_{s \in S^{\prime}} x_{s t}$. The following linear inequalities model the Hall condition for all feasible assignment graphs $G_{t}$ :

$$
\sum_{s \in S^{\prime}} x_{s t} \leq\left|\Gamma\left(S^{\prime}\right)\right| \quad \forall S^{\prime} \subseteq S, t \in T
$$

In general the number of these constraints is exponential and thereby hardly applicable in practice. We will give a proof that the constraints can be reduced to a polynomial number. We show that, for each subset $S^{\prime} \subseteq S_{t}$, there exist a polynomial number of dominating inequalities.

Definition 9. Let $d_{1}^{T} x \leq b_{1}$ and $d_{2}^{T} x \leq b_{2}$ be valid linear inequalities for the time assignment. We say inequality $d_{2}^{T} x \leq b_{2}$ dominates $d_{1}^{T} x \leq b_{1}$, if there exists a $\lambda>0$ such that $d_{1} \leq \lambda d_{2}$ and $\lambda b_{2} \leq b_{1}$.

Remark: In particular, each dominated inequality in a linear programming formulation becomes redundant.

Let $r_{0}$ be a 'dummy' room with capacity $u_{r_{0}}=0$ and let $R_{\max }$ denote the set of rooms that have the highest capacity, as there might exist more than one. Further let $R_{0}=R \cup\left\{r_{0}\right\}-R_{\max }$ and $S_{>r}=\left\{s \in S \mid a_{s}>u_{r}\right\}$ be the set of sessions that have no feasible assignment to room $r$.

Lemma 10. Let $S^{\prime} \subseteq S$ be an arbitrary subset of sessions. Then there exists a room $r^{\prime} \in R_{0}$ such that the following holds:
(i) $S^{\prime} \subseteq S_{>r^{\prime}}$
(ii) $\Gamma\left(S^{\prime}\right)=\Gamma\left(S_{>r^{\prime}}\right)$

Proof. Let $s^{\prime}=\arg \min _{s \in S^{\prime}}\left(a_{s}\right)$ be the smallest session of $S^{\prime}$.
Further let $r^{\prime}=\arg \max _{r \in R: u_{r}<a_{s^{\prime}}}\left(u_{r}\right)$ be the largest room, that can not include session $s^{\prime}$. We show that (i) and (ii) holds for $r^{\prime}$.
(i) Let $s$ be an arbitrary session in $S^{\prime}$. It holds $a_{s} \geq a_{s^{\prime}}>u_{r^{\prime}}$ and therefore $s \in S_{>r^{\prime}}$ by definition of $S_{>r^{\prime}}$.
(ii) Let $r \in \Gamma\left(S^{\prime}\right)$, then there exists a feasible assignment $(s, r)$ with $s \in S^{\prime}$. It holds $s \in S_{>r^{\prime}}$ because of (i). That means $(s, r)$ is a feasible assignment for a session $s \in S_{>r^{\prime}}$ and therefore $r \in \Gamma\left(S_{>r^{\prime}}\right)$.

For the other inclusion let $r \in \Gamma\left(S_{>r^{\prime}}\right)$. It holds $u_{r^{\prime}}<a_{s^{\prime}} \leq u_{r}$, because $r^{\prime}$ is the largest room that can not include $s^{\prime}$ and $u_{r}>u_{r^{\prime}}$ by definition of $r$. That means $\left(s^{\prime}, r\right)$ is a feasible assignment. Since $s^{\prime} \in S^{\prime}$ it follows $r \in \Gamma\left(S^{\prime}\right)$.

Finally, Lemma 10 yields the following dominating inequalities for every $S^{\prime} \subseteq S$ :

$$
\sum_{s \in S^{\prime}} x_{s t} \leq \sum_{s \in S_{>r^{\prime}}} x_{s t} \leq\left|\Gamma\left(S_{>r^{\prime}}\right)\right|=\left|\Gamma\left(S^{\prime}\right)\right| \quad \forall t \in T
$$

We do the reformulation of $\Gamma\left(S_{>r^{\prime}}\right)=\left\{r \in R \mid u_{r}>u_{r^{\prime}}\right\}=$ : $B_{r^{\prime}}$ and add the reformulated linear inequalities to the existing time assignment model formulation:

$$
\begin{equation*}
\sum_{s \in S: a_{s}>u_{r}} x_{s t} \leq\left|B_{r}\right| \quad \forall r \in R_{0}, t \in T \tag{5}
\end{equation*}
$$

Remark: Rooms with equal capacity describe the same inequality. Therefore, we could also refer to a subset of rooms of $R_{0}$ whose capacities are pairwise different.

Corollary 11. There exist a polynomial number of inequalities that dominate the Hall inequalities.

Corollary 12. The inequalities (5) are sufficient for the existence of a matching in the feasible assignment graph $G_{t}$. Thus, a feasible solution of the time assignment model yields the compliance with room capacities at every time slot $t \in T$.

Summarized the main argument for the reducible number of constraints is, that we can exploit the sorting of the attendance values $a_{s}$ and capacities $u_{r}$. If an assignment of a session $s$ to room $r$ is feasible, then an assignment of a smaller session to $r$ is also feasible. This implies a redundancy of inequalities in our model. An illustration to this

feasible (direct) and infeasible (dashed) assignments

Figure 12: Bipartite assignment graph $G_{t}$ with dominating session set $S_{>r^{\prime}} \supseteq S^{\prime}$
idea is given in the next figure.

Remark: An optimal solution of the time assignment, that includes the room capacity constraints, does not necessarily yield an evenly distributed schedule for all EDS sets $j \in J$, as in the previous section. The model is restricted with this constraint.

### 5.1.3 Capacity labeling

If the total number of attendees is sufficiently large, it becomes more difficult to comply with the room capacities. Even though all capacity constraints might be satisfied, as well as all clusters may be evenly distributed over the time slots, the final schedule might look inappropriate for practical usage. In terms of hard capacity constraints, the sessions of one cluster may appear in many different rooms, what is supposed to be avoided in the final schedule. The next figure shows an exemplary time assignment of $S_{c}$ for some cluster $c$. Sessions with a large number of attendees are illustrated by $L$ and sessions with a small number by $S$.

Even though $S_{c}$ has an EDS, this assignment will not work well in practice. If capacity constraints are hard to satisfy, then there is no degree of freedom in the choice of the rooms. That means large sessions must appear in large rooms and, consequently,

Figure 13: Unsuitable time assignment for $S_{c}$
the small sessions must be scheduled to small rooms, because larger rooms are occupied. If we apply a provisional room assignment on this time distribution, the schedule would look similar to the following figure:

Figure 14: Expected room assignment: large sessions to large rooms, small sessions to small rooms

This worst case example shows that big and small sessions are alternating between large and small rooms over the entire length of the conference. That means people, who want to attend this cluster, have to change the room at every consecutive time slot. Furthermore this cluster would probably occupy four different rooms, even if two rooms might be possible. Another disadvantage is the time overlap of the large sessions, because they are more popular in general. Since one participant can visit only one talk at the same time, he would miss the other popular talk. These situations have to be excluded for real-world instances. A more suitable time assignment would be the following:

Figure 15: Even distribution of large and small sessions
In this time assignment, large and small sessions are evenly distributed over the time slots. We generalize this to the fact that an even distribution must additionally hold for sessions with different capacity demand. To achieve such a distribution in our schedule, our approach is to apply the EDS constraints of the previous section to further sets of sessions. In contrast to the last example we need a more precise categorization of the needed capacities of the sessions.

Since we consider feasible assignments only, it holds $a_{s} \leq u_{r}$ for each assignment of a session $s$ to room $r$. Hard capacity constraints will restrict the assignments, such that
$u_{r}$ is generally not much greater than $a_{s}$, because larger rooms are occupied by larger sessions. Let $\mathcal{L}=\left\{u_{r} \mid r \in R\right\}$ be the set of room capacities. We define a capacity labeling as a function

$$
\pi: S \rightarrow \mathcal{L}, s \mapsto \min \left\{u_{r} \mid a_{s} \leq u_{r}\right\}
$$

It describes the minimum possible capacity of an available room that a session can be allocated to. Thus it can be seen as the capacity, where each session 'fits best' in the sense of hard capacity constraints. In particular, all sessions with the same label can be regarded as equal in terms of needed capacities.

Let $S_{c l}=\left\{s \in S \mid c_{s}=c, \pi(s)=l\right\}$ be the session sets that contain all sessions that belong to cluster $c$ and capacity label $l$. Let $\mathcal{L}_{c}=\left\{l \in \mathcal{L} \mid S_{c l} \neq \emptyset\right\}$ be the set of labels that are covered by sessions of cluster $c$. Then, similar to the example before, we apply the EDS constraints to each $S_{c l}$ by should be evenly distributed over the time slots. Therefoupdating the EDS set $\mathcal{S}$ to:

$$
\mathcal{S}=\bigcup_{c \in C}\left\{S_{c}\right\} \cup \bigcup_{c \in C} \bigcup_{l \in \mathcal{L}_{c}}\left\{S_{c l}\right\}
$$

Since we introduce additional variables and constraints for every EDS set, the problem size of the model is enlarged with this step.

## Extended example

We want to present a further example for a fixed cluster $c$, where the sets $S_{c}$ and $S_{c l}$ are evenly distributed, but a better time assignment would be possible. For instance, let us assume that the sessions of $c$ belong to the capacity labels $\mathcal{L}_{c}=\left\{l_{1}, l_{2}, l_{3}, l_{4}\right\}$ with $l_{1}<l_{2}<l_{3}<l_{4}$. From the definition of $\mathcal{S}$ an EDS is applied to the following sets: $S_{c}, S_{c l_{1},}, S_{c l_{2}}, S_{c l_{3}}, S_{c l_{4}}$. In particular $S_{c l_{i}} \subseteq S_{c}$ for all $i=1, \ldots, 4$. An examplary time assignment for $S_{c}$ is shown in the figure below.

Figure 16: Time assignment for labeled sessions of $S_{c}$

The entire set $S_{c}$, as well as each labeling set $S_{c l_{1}}, S_{c l_{2}}, S_{c l_{3}}, S_{c l_{4}}$, is evenly distributed. Once again, we refer to the case of hard capacity constraints. From our previous observations, sessions with lower capacity labels will be scheduled into smaller rooms, while sessions of a higher label will appear in larger rooms. This is because sessions of a higher capacity label will also require a higher minimal capacity. Again, we apply a provisional room assignment to the time distribution of the previous figure, now with respect to capacity labels.

| large room: | $l_{4}$ | $l_{4}$ | $l_{4}$ | $l_{4}$ | $l_{4}$ | $l_{4}$ |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| medium room: | $l_{3}$ | $l_{3}$ | $l_{3}$ | $l_{2}$ | $l_{2}$ | $l_{2}$ | $l_{2}$ | $l_{2}$ | $l_{2}$ |
| small room: |  |  |  |  |  |  |  |  |  |

Figure 17: Hard capacities: high labels to large rooms, low labels to small rooms

The labels $l_{1}, l_{4}$ are characteristically assigned to large and small rooms, while the labels $l_{2}, l_{3}$ could appear in the same room of medium size. This might be possible, if the difference of $l_{2}$ and $l_{3}$ is not too large. In a worse case we can assume, that they cannot share the same room, because shifts due to hard capacity constraints are possible. The number of rooms that one cluster occupies, is to be minimized in the next optimization step. With this time distribution we would probably occupy three rooms for this cluster, but we do not know as the room assignment is done in the end of the entire optimization process. That leads to the question, if we could find a better time assignment for this case. The idea is to integrate sessions of a lower capacity label into the stream of the next higher capacity label. To continue the example, for every $i \in\{1,2,3\}$ the sessions of the labels $l_{i}$ and $l_{i+1}$ should be evenly distributed. Consequently the EDS constraints are applied for these additional sets of sessions. The figure below shows an improved time assignment with respect to additional EDS constraints for successive labels.

Figure 18: EDS for consecutive capacity labels
In contrast to the example before the successive labels $\left(l_{1}, l_{2}\right),\left(l_{2}, l_{3}\right),\left(l_{3}, l_{4}\right)$ are evenly distributed. Note that it is still possible for the labels $l_{2}, l_{3}$ to appear in the same room, because they received an EDS constraint. Unlike the previous time assignment, the labels $l_{1}, l_{2}$ and $l_{3}, l_{4}$ are not assigned in parallel anymore, because they also received an EDS constraint. Now it is possible for them to appear in the same room, if the capacity restrictions would be sufficient. If the integration of $l_{1}, l_{2}$ and $l_{3}, l_{4}$ into one room would be possible, then only two rooms are used for cluster $c$ instead of three.

Inspired from that idea, we enumerate the labels (for which there exists at least one session) of each cluster $c$ by $\mathcal{L}_{c}=\left\{l_{1}, l_{2}, \ldots\right\}$ and update the EDS set $\mathcal{S}$.

$$
\mathcal{S}=\bigcup_{c \in C}\left\{S_{c}\right\} \cup \bigcup_{c \in C} \bigcup_{l \in \mathcal{L}_{c}}\left\{S_{c l}\right\} \cup \bigcup_{c \in C}^{\mid \bigcup_{i=1}^{\left|\mathcal{L}_{c}\right|-1}}\left\{S_{c l_{i}} \cup S_{c l_{i+1}}\right\}
$$

Apart from $\mathcal{S}$ the Mixed Integer Program remains the same, as it was introduced in Section 5.1.1 where $\mathcal{S}$ was defined with help of an index set $J$.

Summarized, the capacity labeling contributes to a time-dependent presorting by the needed room capacities of each session. This is supposed to provide a better room assignment in the next optimization step. It is an intuitional approach that we believe to improve the later solutions. For our contribution in this thesis we have not proven, if a time assignment with labeling constraints would always yield a better schedule. But from our observations, they contribute significantly to a better scheduling result. An computed example with and without labeling constraints is given in the section 'computational results'.

### 5.1.4 Lower bound constraints

The time assignment model focuses on the even distribution of all session sets $S_{j} \in \mathcal{S}$ with $j \in J$. For each of these sets we applied EDS constraints. A further advantage of the EDS constraints is that there exist strong lower bounds.

Let $S_{j} \in \mathcal{S}$ be a set of sessions that belongs to an EDS and let $U_{j}, y_{j t}$ and $z_{j d}$ be the corresponding variables, as they were introduced in Section 5.1.1. Further let $N=\min _{d \in D}\left|T_{d}\right|$. The objective function of the time assignment model reads as:

$$
\min \sum_{j \in J}\left(\lambda_{1} U_{j}+\lambda_{2} \sum_{t \in T} y_{j t}-\lambda_{3} \sum_{d \in D} z_{j d}\right)
$$

Definition 13. Consider the following parameters:
(i) $U_{j}^{*}=\left\lceil\frac{\left|S S_{j}\right|}{|T|}\right\rceil$
(ii) $y_{j}^{*}=\left|S_{j}\right| \bmod |T|$
(iii) $z_{j}^{*}=\left\lfloor\frac{\left|S_{j}\right| \bmod |T|}{N}\right\rfloor$

Claim 14. Every feasible solution of the time assignment and every $j \in J$ satisfies the following inequalities:
(1) $U_{j}^{*} \leq U_{j}$
(2) $\quad \lambda_{1} U_{j}^{*}+\lambda_{2} y_{j}^{*}-\lambda_{3} z_{j}^{*} \leq \lambda_{1} U_{j}+\lambda_{2} \sum_{t \in T} y_{j t}-\lambda_{3} \sum_{d \in D} z_{j d}$

Proof. (1) $U_{j}$ is the upper bound on the number of sessions of $S_{j}$ at each time slot. Each session of $S_{j}$ has to be scheduled, so the minimum number of sessions at each time slot is $\frac{\left|S_{j}\right|}{|T|}$. Since the number of scheduled sessions at each time slot is integral, it holds $\left\lceil\frac{\left|S_{j}\right|}{|T|}\right\rceil=U_{j}^{*} \leq U_{j}$.
(2) Proposition 5 says that an EDS yields the optimal objective value for each $S_{j}$. Therefore, we show that the lower bound in (2) is the objective value of an EDS of $S_{j}$. The minimal possible value of $U_{j}$ is $U_{j}^{*}$, what was already shown in (1). Especially in an EDS it holds $U_{j}=U_{j}^{*}$. There are exactly $\left|S_{j}\right| \bmod |T|$ leftover time slots, where $S_{j}$ is maximal. Each bundled day of $S_{j}$ consists of at least $N$ maximal time slots. That means from the number of maximal time slots in the EDS, we can create at most $\left\lfloor\frac{\left|S_{j}\right| \bmod |T|}{N}\right\rfloor$ bundled days. As these are the best possible values for each of the variables in an EDS, the inequality (2) yields a lower bound for $S_{j}$.

For each $j \in J$ we can add the following constraints to the time assignment model:

$$
\begin{array}{ll}
U_{j}^{*} \leq U_{j} & \forall j \in J \\
\lambda_{1} U_{j}^{*}+\lambda_{2} y_{j}^{*}-\lambda_{3} z_{j}^{*} \leq \lambda_{1} U_{j}+\lambda_{2} \sum_{t \in T} y_{j t}-\lambda_{3} \sum_{d \in D} z_{j d} & \forall j \in J \tag{7}
\end{array}
$$

From our observations, the lower bound constraints contribute significantly to the computation process. In our test instances we obtained smaller integrality gaps by adding these lower bounds to the model formulation such that the time assignment model was almost optimally solvable.

### 5.1.5 Chairman constraints

Every session at the ISMP conference has a chairman who gives a short introduction about the talks and the speakers in the session. A chairman is also able to give a talk at the conference, what does not necessarily have to be contained in the session he attends as chairman. This special case, where a chairman must be present in several sessions at the same time, has to be excluded. Therefore let $S_{p}^{t a l k}$ be the set of sessions, where a person $p \in P$ gives a talk and $S_{p}^{\text {chair }}$ the set of sessions $p$ attends as chairman. For our case at ISMP the number of talks a person may give was restricted to one, i.e. $\left|S_{p}^{t a l k}\right|=1$. The avoidance of time overlaps of the corresponding sessions is modeled by the linear inequality:

$$
\begin{equation*}
\sum_{s \in S_{p}^{t a l k} \cup S_{p}^{c h a i r}} x_{s t} \leq 1 \quad \forall t \in T, p \in P:\left|S_{p}^{\text {talk }} \cup S_{p}^{\text {chair }}\right|>1 \tag{8}
\end{equation*}
$$

### 5.1.6 Individual scheduling requests

During the planning process of large conferences, like the ISMP 2012, there occur a series of individual scheduling requests from the conference participants. We figured out three main types of requests: interval, no overlap and precedence requests. Each type of request is modeled as additional linear inequality in the time assignment.

## Interval requests

An interval requests asks to schedule a session within a certain interval of time slots. Therefore let $S_{I}$ denote the set of sessions that belong to an interval request and let $\left[t_{s}^{-}, t_{s}^{+}\right]$be the desired time slot interval. The following inequality ensures that these sessions are scheduled within the requested interval:

$$
\begin{equation*}
\sum_{t \in\left[t_{s}^{-}, t_{s}^{+}\right]} x_{s t}=1 \quad \forall s \in S_{I} \tag{9}
\end{equation*}
$$

## No overlap requests

The no overlap requests ask that a pair of sessions $\left(s_{1}, s_{2}\right)$ is not scheduled not in parallel. Here let $S_{N} \subseteq S^{2}$ be the set of session pairs that must not overlap. The requests are modeled by the linear inequalities:

$$
\begin{equation*}
x_{s_{1} t}+x_{s_{2} t} \leq 1 \quad \forall\left(s_{1}, s_{2}\right) \in S_{N}, t \in T \tag{10}
\end{equation*}
$$

## Precedence requests

Precedence requests constrain a session to be scheduled before another session. In general, such requests occur, when there are dependencies between two sessions according to their title and content. For example, there might be precedence constraints between sessions with the titles: Scheduling I, Scheduling II, Scheduling III that have to be scheduled in direct succession.

We differentiate between hard and soft precedence constraints. Hard constraints state that two sessions have to appear at two successive time slots, while soft constraints allow further time slots in between. Let $S_{P}^{\text {hard }}, S_{P}^{s o f t} \subseteq S^{2}$ denote the set of session pairs with hard and soft precedence constraints. Each element $\left(s_{1}, s_{2}\right)$ indicates that $s_{1}$ must be scheduled before $s_{2}$. Let $T^{\prime}=T-\max (T)$, then hard and soft precedence constraints are modeled as:

$$
\begin{array}{ll}
x_{s_{1} t}=x_{s_{2} t+1} & \forall\left(s_{1}, s_{2}\right) \in S_{P}^{\text {hard }}, t \in T^{\prime}
\end{array} \quad \text { (11) } \quad \text { (hard precedence) }
$$

### 5.1.7 Even attractivity distribution

At each conference there are some talks that are more popular than others, because of different interests in specific talks, famous speakers or new results in research. Obviously,
more people are attracted to attend those sessions. Therefore it is important to have an equal amount of interesting talks available at each time slot to establish an attractive scientific program for the whole conference.

To determine a degree of popularity for each session, we have to distinguish between 'attractive' and 'less attractive' sessions. In that sense, we introduce an attractivity coefficient $\alpha_{s}>0$ that denotes the attractivity of each session $s$. The higher the value, the more pople are attracted to attend this session.

There are many possibilities to define this value. For the ISMP, we used a weighted sum of potential attractivity indicators to obtain $\alpha_{s}$, like: number of submitted talks for $c_{s}$, stated preferences at the webpage registration and empirical attendee numbers of a previous conference. Since the attractivity of a session is in the eye of the beholder, we define $\alpha_{s}$ to be the attractivity of an average participant. The values of $\alpha_{s}$ are now used to implement an even attractivity distribution over the length of the conference.

For that, we define the variable $A_{\min } \geq 0$, which is a lower bound on the sum of attractivities at every time slot $t \in T$. Similarly, the variable $A_{\max } \geq 0$ yields an upper bound for every time slot $t \in T$. The even attractivity distribution is modeled by linear inequalities and an additional term in the objective function:

$$
\begin{align*}
& A_{\min } \leq \sum_{s \in S} \alpha_{s} x_{s t} \quad \forall t \in T  \tag{13}\\
& A_{\max } \geq \sum_{s \in S} \alpha_{s} x_{s t} \quad \forall t \in T \tag{14}
\end{align*}
$$

Thus, for each pair of time slots the absolute difference in the sum of attractivities is at most $A_{\max }-A_{\min }$. Since the attractivities should be evenly distributed, $A_{\max }-A_{\min }$ is minimized. Finally we add the following term to the objective function with weight coefficient $\lambda_{4} \geq 0$ :

$$
\min \quad \lambda_{4}\left(A_{\max }-A_{\min }\right)
$$

The coefficient $\lambda_{4}$ can be adjusted when looking at the produced schedules.

In Section 5.2 we will use the property of an even attractivity distribution to approximate the uncertain number of attendees $a_{s}$ by use of a stochastic model. We will see that a balanced attractivity distribution even has good side effects.

### 5.2 Robustness of capacity compliance

In the previous subsection we introduced attractivity values $\alpha_{s}$ to determine the average interest in every session $s \in S$ at the conference. With respect to these values we derive a stochastic model to determine the number of attendees $a_{s}$ for every session. In the real world, as well as in our model concept, the number of attendees is an uncertain quantity. In our stochastic modeling approach, the needed capacity of every session is calculated
with use of a nonlinear model. We will give an approach to deal with the nonlinearity of that model, as well as the integration to the existing time assignment formulation.

First, let $n$ denote the total number of attendees at the conference or, respectively, the maximum number of attendees at a specific time slot. The total number of attendees may vary between the time slots. But from the perspective of an organizer, we have to assume that each participant takes part in the whole conference. Therefore, we suppose that $n$ attendees are present at each time slot. We further assume that every person has average preferences regarding the choice of his session, that means his choice between the sessions depends on the attractivity coefficients $\alpha_{s}$ and we also suppose that each participant makes his choice independently from the other participants. It is expected that every participant chooses a session at each time slot $t$, so the choice depends on the attractivities $\alpha_{s}$ of the sessions, that are scheduled at $t$. Consequently, we define the probability to choose some session $s$ at time slot $t$, as the ratio between $\alpha_{s}$ and the total attractivity at $t$. An illustration to the choice modeling is given in Figure 18.

Figure 19: Selection probabilities $p_{s}(x)$ of a participant $p$ for two different time assignments
The figure shows two different time assignments for time slot $t$. Since the probability to choose one particular session depends on the selection of sessions that are available at $t$, the choice probabilities may change for two different time assignments, as for $s_{2}, s_{3}$ in the example. From these assumptions we define the following stochastic concepts:

Definition 15. Let $\Omega=\left\{\omega_{1}, \omega_{2}\right\}$ be the decision set to choose ( $\omega_{1}$ ) or not to choose a session $\left(\omega_{2}\right)$. For all sessions $s \in S$ and all participants $j \in P$ let $X_{s j}: \Omega \rightarrow\{0,1\}$ be discrete and stochastically independent random variables that are defined as

$$
X_{s j}(\omega)= \begin{cases}1, & \omega=\omega_{1} \\ 0, & \omega=\omega_{2}\end{cases}
$$

$X_{s j}=1$ states that participant $j$ chooses session s and $X_{s j}=0$ otherwise. Further let $S_{t}$ denote the set of sessions at $t$ and $t(s)$ be the time slot, when session $s$ is scheduled.

It is assumed that there exists at least one session at each time slot, i.e. $\sum_{s \in S} x_{s t} \geq 1$ for all $t \in T$. We define the discrete probability function $\mathbb{P}: \Omega \rightarrow[0,1]$ by:

$$
\begin{aligned}
& \mathbb{P}\left(X_{s j}=1\right)=\frac{\alpha_{s}}{\sum_{s^{\prime} \in S_{t(s)}} \alpha_{s^{\prime} x_{s^{\prime} t(s)}}}=p_{s}(x) \\
& \mathbb{P}\left(X_{s j}=0\right)=1-p_{s}(x) .
\end{aligned}
$$

Then $p_{s}(x)$ denotes the probability that participant $j$ will attend session s. Moreover, each participant chooses session $s$ with the same probability. Since $\alpha_{s}$ refers to average preferences.

Note that $\alpha_{s}$ referred to average preferences and $\alpha_{s}>0$ for all $s \in S$. It is easy to see that $\mathbb{P}$ defines a probability function. We also notice that $p_{s}(x)$ is a rational function in $x$ and especially non-linear. This can be interpreted by the fact that the choice on session $s$ depends on the selection of sessions that are available at time slot $t(s)$. This selection is determined by the decision variables $x_{s t}$ of the time assignment.

Definition 16. Each random variable $X_{s j}$ has a value of either one or zero (success or no success). Therefore, $X_{s j}$ defines a Bernoulli trial. The sequence $X_{s 1}, \ldots, X_{s n}$ over all participants implies a Bernoulli process for every session s. We define the random variable $X_{s}$ as the number of successes in this Bernoulli process. In the model, this is analogous to the number of participants who choose session s.

$$
X_{s}=\sum_{j \in P} X_{s j}
$$

In particular, we obtain the binomial distribution function. That yields the probability that exactly $k$ persons will choose session s:

$$
\mathbb{P}\left(X_{s}=k\right)=\binom{n}{k} p_{s}(x)^{k}\left(1-p_{s}(x)\right)^{n-k}=: B\left(k, n, p_{s}(x)\right)
$$

Similarly, the cumulative distribution function yields the probability that at most $k$ persons attend session s:

$$
\mathbb{P}\left(X_{s} \leq k\right)=\sum_{j=0}^{k}\binom{n}{j} p_{s}(x)^{j}\left(1-p_{s}(x)\right)^{n-j}=: F\left(k, n, p_{s}(x)\right)
$$

Note that the probabilities still depend on the decision variables $x_{s t}$.
From these definitions we want to determine the number of attendees $a_{s}$. One possibility would be to choose the expected value of $X_{s}$, that is:

$$
a_{s}(x)=\mathbb{E}\left[X_{s}\right]=n \cdot p_{s}(x)
$$

But in general, the use of expected values will not work well in practice. This is because the probability that some session exceeds the expected value is quite large. For our considerations we want to have a degree of certainty that the calculated number of attendees will not be exceeded. Therefore, we define a certainty value $\gamma_{s} \in[0,1]$ which defines the probability, that session $s$ will not be exceeded. Thus, the number of attendees is defined as the minimum number $k$, such that the probability that at most $k$ participants choose session $s$ is greater than $\gamma_{s}$ :

$$
\begin{aligned}
& a_{s}\left(\gamma_{s}, x\right)=\min \left\{k \in \mathbb{N} \mid \mathbb{P}\left(X_{s} \leq k\right) \geq \gamma_{s}\right\} \\
\Leftrightarrow & a_{s}\left(\gamma_{s}, x\right)=\min \left\{k \in \mathbb{N} \mid F\left(k, n, p_{s}(x)\right) \geq \gamma_{s}\right\}
\end{aligned}
$$

Two problems remain with this formulation. First, the total needed capacity increases for higher values of $\gamma_{s}$. If we choose them arbitrarily large, then the capacity constraints might get infeasible. We further assume that $\gamma_{s}$ is chosen, such that all capacity constraints are satisfied. The next problem is the nonlinearity of the number of attendees $a_{s}\left(\gamma_{s}, x\right)$, because the inequality (5), see Section 5.1.2, uses constant values for $a_{s}$.

One important observation is, if we use a constant value $\tilde{a}_{s} \geq a_{s}\left(\gamma_{s}, x\right)$, then the room capacity will also be sufficient for the stochastic values $a_{s}\left(\gamma_{s}, x\right)$, because we are considering feasible assignments only, that means:

$$
a_{s}\left(\gamma_{s}, x\right) \leq \tilde{a}_{s} \leq u_{r} \Rightarrow a_{s}\left(\gamma_{s}, x\right) \leq u_{r} \Rightarrow(s, r) \text { is a feasible assignment. }
$$

If we would use values smaller than $a_{s}\left(\gamma_{s}, x\right)$, then it is not ensured that capacities are still sufficient.

In our approach we create upper bound values $\tilde{a}_{s}$ for every session $s$, what implies the compliance with room capacities for the stochastic values. The disadvantage of upper bounds is the increase in the needed room capacities. It is necessary that the gap between $\tilde{a}_{s}$ and $a_{s}\left(\gamma_{s}, x\right)$ is kept tight. We present an approximation of $\approx\left(1+2 \epsilon+\epsilon^{2}\right)$ $(\epsilon \geq 0)$ on the stochastic values. This approach makes use of the approximability of an even attractivity distribution which was introduced in Section 5.1.6.

Let $\epsilon \geq 0$ and let $C=\frac{1}{|T|} \sum_{s \in S} \alpha_{s}$ be the mean attractivity at each time slot. The constant probability to choose session $s$ is defined as $\tilde{p}_{s}=\frac{\alpha_{s}}{C}(1+\epsilon)$. We apply the following inequalities to the existing time assignment model:

$$
\begin{equation*}
C \leq A_{\min }(1+\epsilon) \tag{15}
\end{equation*}
$$

$$
\begin{equation*}
A_{\max } \leq C(1+\epsilon) \tag{16}
\end{equation*}
$$

Proposition 17. Let $x$ be a feasible solution of the time assignment with respect to inequalities (15) and (16). Then $\tilde{p}_{s}$ yields an $\left(1+2 \epsilon+\epsilon^{2}\right)$-approximation on the stochastic probabilities $p_{s}(x)$ for all $s \in S$, that means $p_{s}(x) \leq \tilde{p}_{s} \leq p_{s}(x)\left(1+2 \epsilon+\epsilon^{2}\right) \quad \forall s \in S$.

Proof. First, we show $p_{s}(x) \leq \tilde{p}_{s}$ :

$$
p_{s}(x)=\frac{\alpha_{s}}{\sum_{s^{\prime} \in S} \alpha_{s^{\prime}} x_{s^{\prime} t(s)}} \leq \frac{\alpha_{s}}{A_{\min }} \leq \frac{\alpha_{s}}{C}(1+\epsilon)=\tilde{p}_{s}
$$

The first inequality yields constraint (13) of the time assignment model, and the second inequality follows from constraint (15).

The second inequality $\tilde{p}_{s} \leq p_{s}(x)\left(1+2 \epsilon+\epsilon^{2}\right)$ follows from :

$$
\tilde{p}_{s}=\frac{\alpha_{s}}{C}(1+\epsilon) \leq \frac{\alpha_{s}}{A_{\max }}(1+\epsilon)^{2} \leq \frac{\alpha_{s}}{\sum_{s^{\prime} \in S} \alpha_{s^{\prime}} x_{s^{\prime} t(s)}}(1+\epsilon)^{2}=p_{s}(x)(1+\epsilon)^{2}=p_{s}(x)\left(1+2 \epsilon+\epsilon^{2}\right)
$$

The first inequality is a direct consequence of constraint (16) and the second follows from inequality (14).

Remark 18. Note that we compute a solution of the time assignment model with respect to fixed parameters $\epsilon \geq 0$ and $\gamma_{s} \in[0,1]$. For arbitrary small $\epsilon$ the optimization model may get infeasible, because a completely even attractivity distribution is not possible. Also for values of $\gamma_{s} \rightarrow 1$, the model may also get infeasible, as the needed capacities will increase.

If we add inequalities (15) and (16) to our model, then we obtain an approximation factor of $\left(1+2 \epsilon+\epsilon^{2}\right)$ on the probability to choose session $s$. In the following we use the approximated constant probabilities $\tilde{p}_{s}$ to define a constant upper bound on the number of attendees $\tilde{a}_{s}$ with respect to the certainty value $\gamma_{s}$ :

$$
\tilde{a}_{s}\left(\gamma_{s}\right)=\min \left\{k \in \mathbb{N} \mid F\left(k, n, \tilde{p}_{s}\right) \geq \gamma_{s}\right\}
$$

Proposition 19. For arbitrary $\gamma_{s} \in[0,1]$, the constant $\tilde{a}_{s}\left(\gamma_{s}\right)$ defines an upper bound for the stochastic values $a_{s}\left(\gamma_{s}, x\right)$, that means:

$$
a_{s}\left(\gamma_{s}, x\right) \leq \tilde{a}_{s}\left(\gamma_{s}\right) \quad \forall s \in S
$$

Proof. By proposition 17 it holds $p_{s}(x) \leq \tilde{p}_{s}$. For fixed $k$ and $n$ the functional value of the cumulative binomial distribution function $F$ decreases with increasing probability, that means $F\left(k, n, \tilde{p}_{s}\right) \leq F\left(k, n, p_{s}(x)\right)$. Now, let $k=a_{s}\left(\gamma_{s}, x\right)$ and $\tilde{k}=\tilde{a}_{s}\left(\gamma_{s}\right)$. We assume $\tilde{a}_{s}\left(\gamma_{s}\right)<a_{s}\left(\gamma_{s}, x\right)$ or $\tilde{k}<k$ respectively. By definition of $a_{s}\left(\gamma_{s}, x\right)$ and $\tilde{a}_{s}\left(\gamma_{s}\right)$, it holds $\gamma_{s} \leq F\left(\tilde{k}, n, \tilde{p}_{s}\right)$ and $\gamma_{s} \leq F\left(k, n, p_{s}(x)\right)$. From that, it follows:

$$
\gamma_{s} \leq F\left(\tilde{k}, n, \tilde{p}_{s}\right) \leq F\left(\tilde{k}, n, p_{s}(x)\right)<F\left(k, n, p_{s}(x)\right)
$$

The last inequality uses the strict monotony of the cumulative binomial distribution function. That forms a contradiction on $k$ being minimal for $F\left(k, n, p_{s}(x)\right) \geq \gamma_{s}$, since it also holds for $\tilde{k}<k$. Consequently it follows: $k \leq \tilde{k} \Leftrightarrow a_{s}\left(\gamma_{s}, x\right) \leq \tilde{a}_{s}\left(\gamma_{s}\right)$.

We found constant upper bound values on the stochastic number of attendees. That means if we choose the values $\tilde{a}_{s}\left(\gamma_{s}\right)$ instead of the stochastic values $a_{s}\left(\gamma_{s}, x\right)$, then every feasible assignment of sessions to rooms will also be feasible for the stochastic values.

## Quality of the upper bound

Now we want to make a statement concerning the quality of the upper bound. As higher values of $\tilde{a}_{s}\left(\gamma_{s}\right)$ will increase the needed capacities, it would be helpful to have this bound as tight as possible. To show the approximation quality, we transform problem of the discrete binomial distribution to continuous intervals, using the normal distribution. For large $n$, it is known that the normal distribution approximates the binomial distribution for given expected value and variance of the binomial distribution. We will show that the transformation to the continuous case yields an approximation of $\tilde{a}_{s}\left(\gamma_{s}\right) \leq a_{s}\left(\gamma_{s}, x\right)\left(1+2 \epsilon+\epsilon^{2}\right)$, what then nearly corresponds to the discrete case.

At first, we define the cumulative distribution function of the standard normal distribution:

$$
\Phi(x)=\frac{1}{\sqrt{2 \pi}} \int_{-\infty}^{x} e^{-y^{2} / 2} d y
$$

To evaluate the cumulative normal distribution function in a certain point $x$ we use the known substitution $\Phi\left(\frac{x-\mu}{\sigma}\right)$ with given expected value $\mu$ and variance $\sigma^{2}$. In particular, the binomial distribution obtains $\mu=n p$ and $\sigma^{2}=n p(1-p)$. For large $n$ ther is the approximation.

$$
F(k, n, p) \approx \Phi\left(\frac{k-\mu}{\sigma}\right)
$$

Let $\epsilon^{\prime}=2 \epsilon+\epsilon^{2}$. As already shown in proposition 17 , it holds $p_{s}(x) \leq \tilde{p}_{s} \leq p_{s}(x)(1+$ $\left.\epsilon^{\prime}\right)$. We abuse notation and denote $p=p_{s}(x)$ and $\tilde{p}=\tilde{p}_{s}$. The expected values and variances of the binomial distribution for $p$ and $\tilde{p}$ are known to be the following:

$$
\begin{array}{ll}
\mu=n p, & \sigma^{2}=n p(1-p) \\
\tilde{\mu}=n \tilde{p}, & \tilde{\sigma}^{2}=n \tilde{p}(1-\tilde{p})
\end{array}
$$

Let $\gamma_{s} \in[0,1]$ be the certainty value. There are values $a, \tilde{a} \in \mathbb{R}$ for which $\Phi\left(\frac{a-\mu}{\sigma}\right)=$ $\Phi\left(\frac{\tilde{a}-\tilde{\mu}}{\tilde{\sigma}}\right)=\gamma_{s}$. These values correspond to the number of attendees in the continuous case. The next proposition refers to the case of $0.5 \leq \gamma_{s}$, what is usual for practical problems, so we actually do not restrict the problem here.

Proposition 20. For a given certainty value $\gamma_{s} \in[0.5,1]$, let $a, \tilde{a} \in \mathbb{R}$ with $\Phi\left(\frac{a-\mu}{\sigma}\right)=\Phi\left(\frac{\tilde{a}-\tilde{\mu}}{\tilde{\sigma}}\right)=\gamma_{s}$. Then $\tilde{a}$ approximates a within a factor of $\left(1+\epsilon^{\prime}\right)$.
Proof. Equally to the observations of proposition $17, \Phi$ yields, at some fixed, point smaller functional values for higher probabilities. Therefore it holds $a \leq \tilde{a}$, similar to the discrete case.

For the other inequality, it holds $a-n p=a-\mu \geq 0$ because of $\gamma_{s} \geq 0.5$. We further know that $\tilde{p} \leq p\left(1+\epsilon^{\prime}\right)$. We do the following assessment:

$$
\begin{aligned}
& a-n p \leq \sqrt{\frac{1-p}{1-\tilde{p}}}(a-n p) \leq \sqrt{\frac{\left(1+\epsilon^{\prime}\right) n p(1-p)}{n \tilde{p}(1-\tilde{p})}}(a-n p) \\
& \leq \sqrt{\frac{n p(1-p)}{n \tilde{p}(1-\tilde{p})}}\left(1+\epsilon^{\prime}\right)(a-n p) \leq \sqrt{\frac{n p(1-p)}{n \tilde{p}(1-\tilde{p})}}\left(a\left(1+\epsilon^{\prime}\right)-n \tilde{p}\right) \\
& \Leftrightarrow \frac{a-n p}{\sqrt{n p(1-p)}} \leq \frac{a\left(1+\epsilon^{\prime}\right)-n \tilde{p}}{\sqrt{n \tilde{p}(1-\tilde{p})}}
\end{aligned}
$$

With use of the last inequality we obtain:

$$
\gamma_{s}=\Phi\left(\frac{\tilde{a}-n \tilde{p}}{\sqrt{n \tilde{p}(1-\tilde{p})}}\right)=\Phi\left(\frac{a-n p}{\sqrt{n p(1-p)}}\right) \leq \Phi\left(\frac{a\left(1+\epsilon^{\prime}\right)-n \tilde{p}}{\sqrt{n \tilde{p}(1-\tilde{p})}}\right)
$$

Looking at the left- and right-hand side, the monotony of $\Phi$ yields $\tilde{a} \leq a\left(1+\epsilon^{\prime}\right)$.
Summarized, the transformation of the problem to continuous intervals yields an approximation factor of $\epsilon^{\prime}=1+2 \epsilon+\epsilon^{2}$ for $\tilde{a}_{s}$. We do not achieve this approximation in general for the binomial distribution. But since for large $n$, the approximation quality of $\Phi\left(\frac{\tilde{a}-\tilde{\mu}}{\tilde{\sigma}}\right) \approx F(\tilde{a}, n, \tilde{p})$ increases, we can conclude that it also yields a sufficient good approximation for our considerations. We tested instances of $n=500-2000$ participants, where values of $\epsilon=0.008$ (approximation factor of $\approx 1.016$ ) were achievable for the ISMP instance and for general instances $\epsilon \approx 0.03$ is a realistic guideline for larger conferences.

The following table illustrates the previous assessments for the number of attendees concerning the two probabilities $p_{s}(x)$ and $\tilde{p}_{s}$.

Figure 20: cumulative normal distribution for session $s$ with probabilities $p_{s}(x) \leq \tilde{p}_{s}$

## Relation to the total capacity demand

If we want to introduce a general certainty value $\gamma$, which states that no session of the conference will exceed the capacity, then we have to choose values with $\prod_{s \in S} \gamma_{s} \geq \gamma$. One simple possibility is to define $\gamma_{s}:=\gamma^{\frac{1}{|S|}}$. The following tables show the increase in total capacity with respect to the certainty value $\gamma$ and approximation factor $\epsilon$. The
data refers to the ISMP problem instance with $n=1500$ participants.

For fixed $\epsilon \geq 0$, the total capacity demand grows slowly for smaller values of $\gamma$. The absolute certainty that no session exceeds the capacity $(\gamma=1)$ occurs, when $a_{s}=n$ for all $s \in S$, what would be $|S| \cdot n=892.500$ in the left figure. Therefore, the total capacity demand grows rapidly for $\gamma$ close to one. In general, $\gamma=1$ is not achievable for real-world instances. In contrast to that, for fixed certainty value $\gamma$ the total capacity demand grows almost linear with approximation factor $\epsilon$. Since we want to achieve values of $\epsilon$ close to zero, the problem is to find a small value of $\epsilon$ such that the model remains feasible. But also for small $\epsilon$ we restrict the schedule in the property that the attractivity at each time slot is constrained to deviate from the mean attractivity by only $\epsilon$. The goal is to find a good balance between the values of $\gamma$ and $\epsilon$ by testing different configurations of the underlying problem instance.

## 6 Stream Assignment

The second optimization step is called the stream assignment that uses the solution of the time assignment to connect sessions to streams. Formally, a stream is a sequence
$\left(s_{1}, \ldots, s_{T}\right)$ of sessions, that take place in the same room. In particular, a stream has no assignment to a certain room yet, as it only contains sessions in temporal order. A stream can also be empty, that means it contains no sessions.

This model focuses on the minimization of used streams of each cluster, what implies to find a distribution over the minimum possible number of rooms. Another objective is, that the sessions of one cluster should occur successive in the same stream. We will call this successive occurrence of a certain cluster in a stream, a time connection. More detailed, a cluster $c$ has a time connection at time slot $t$, if there are sessions $s, s^{\prime} \in S_{c}$ that appear successive in the same stream at time slots $t$ and $t+1$. In the objective, the number of time connections is to be maximized.

A first observation shows, that both objectives are not equivalent to each other. Let us have a look at the following examples of a stream assignment. In Figure 21 we see that cluster $c$ occupies a minimum number rooms, what is obviously not sufficient for a maximum number of time connections, even if $c$ has an EDS. Considering the other case, if we have a maximal number of time connections, it is also not ensured that the number of rooms will be minimal, see Figure 22.

Figure 21: Minimal number of used rooms for $S_{c}$

Figure 22: Maximal number of time connections for each cluster $c=1,2,3,4$

In the next sections we present a Mixed-Integer-Program that assigns every session to a stream with respect to the mentioned objectives. Furthermore, we will introduce a small heuristic that modifies the solution of the stream assignment, such that a further set of constraints can be validated.

### 6.1 Mathematical Optimization Model

In this next part we introduce the MIP formulation to that problem. We will abuse notation and choose similar variables, like in the time assignment. Both models are regarded as completely independent from each other in terms of notation. Even though we mentioned that, by definition, a stream is independent from any room, we will use an assignment of sessions to rooms in this model. That is because we have to ensure that the stream assignment also satisfies the room capacities. Therefore, this model approach
is regarded as an allocation to rooms, but the final room of each stream may change during the last optimization step, the 'room assignment'.

## Mixed Integer Program

From the solution of the time assignment, we obtained disjoint sets $S_{1}, \ldots, S_{T}$, where $S_{t}$ contains all sessions that are scheduled at time slot $t \in T$.

Further let $A=\left\{(s, r) \mid s \in S, r \in R, a_{s} \leq u_{r}\right\}$ be the set of feasible assignments from sessions to rooms. We define the binary variable $x_{s r}$ for all feasible assignments $(s, r) \in A$ :

$$
x_{s r}= \begin{cases}1, & \text { if session } s \text { takes place in room } r \\ 0, & \text { otherwise }\end{cases}
$$

For each $c \in C$, the sessions of $S_{c}$ are supposed to occupy a minimum number of rooms. Therefore, we introduce the decision variable $z_{c r}$ that takes on the value 1 , if any session of cluster $c$ takes place in room $r$, and 0 otherwise. To model the time connections, we define the binary variable $y_{c r t}$ that has the value 1 , if there exist two sessions of cluster $c$ in room $r$ at time slots $t$ and $t+1$. Further let $R_{s}=\left\{r \in R \mid a_{s} \leq u_{r}\right\}$ denote the set of feasible rooms for session $s$ and $S_{r}=\left\{s \in S \mid a_{s} \leq u_{r}\right\}$ the set of feasible sessions for room $r$. For simplification, let $S_{r t}=S_{r} \cap S_{t}$ and $S_{c r t}=S_{c} \cap S_{r} \cap S_{t}$. We further define $T^{\prime}=T-\max (T)$ and $\lambda \in[0,1]$ is a weight coefficient between the two objectives.

$$
\begin{array}{lll}
\min & \lambda \sum_{c \in C} \sum_{r \in R} z_{c r}-(1-\lambda) \sum_{c \in C} \sum_{r \in R} \sum_{t \in T^{\prime}} y_{c r t} \\
\text { s.t. } & \sum_{r \in R_{s}} x_{s r}=1 & \forall s \in S \\
& \sum_{s \in S_{r t}} x_{s r} \leq 1 & \forall r \in R, t \in T \\
& \sum_{s \in S_{c r t}} x_{s r}-z_{c r} \leq 0 & \forall c \in C, r \in R, t \in T \\
& y_{c r t}-\sum_{s \in S_{c r t}} x_{s r} \leq 0 & \forall c \in C, r \in R, t \in T^{\prime}  \tag{4}\\
& y_{c r t}-\sum_{s \in S_{c r t+1}} x_{s r} \leq 0 & \forall c \in C, r \in R, t \in T^{\prime} \\
& \\
& x_{s r} \in\{0,1\} & \forall s \in S, r \in R \\
y_{c r t} \in\{0,1\} & \forall c \in C, r \in R, t \in T^{\prime} \\
z_{c r} \in\{0,1\} & \forall c \in C, r \in R
\end{array}
$$

The objective function minimizes the number of rooms that are occupied by every cluster, as well as it maximizes the number of time connections of each cluster. The value of $\lambda$ weigth the importance between the objectives. Inequalities (1) state, that every session is assigned to a feasible room. At every time slot, each room can be occupied by at most one feasible assignment (2). Constraint (3) says, if a session of cluster $c$ is scheduled in room $r$ at any time slot, then cluster $c$ occupies room $r$. The time connections are modeled with constraints (4) and (5): if there is a time connection of cluster $c$ in room $r$ at time slot $t$, then also sessions of cluster $c$ must be scheduled in room $r$ at time slots $t$ and $t+1$. Note that the variables $y_{c r t}, z_{c r}$ can be relaxed to: $0 \leq z_{c r} \leq 1$ and $0 \leq y_{c r t} \leq 1$.

### 6.2 Computational complexity of the stream assignment

The solving time of the entire stream assignment model was too high for our understanding of practical implementation. We believe that the high computation time results from occurring symmetries in the model. More precise, there are assignments that do not affect the objective function. There it makes no difference whether to choose the one or the other room for a particular cluster. This makes the solving process more complex.

We tested several modifications of the stream assignment MIP. It turned out, that if we delete constraints (3) and the variables $z_{c r}$ from the model, then the running time improves greatly. That means, when only the time connections ( $y_{c r t}$ variables) are maximized, then the stream assignment is nearly optimally solvable in short time. In most cases this also leads to a surprisingly good schedule. But as already mentioned, a maximal number of time connections does not exclude that the sessions of one cluster can be widely distributed over the set of rooms. This may result in long walking distances between parallel sessions of equal clusters. Our solutions were taken from the relaxed model.

### 6.3 Cluster swap heuristic

A solution of the stream assignment MIP yields an assignment of all sessions to streams. In the model, every stream was associated with a room to ensure the compliance with room capacities, that means it holds $a_{s} \leq u_{r}$ for each assignment of a session $s$ to a room $r$. Let us consider a time slot $t$, where two sessions $s_{1}, s_{2} \in S_{c}$ of cluster $c$ are scheduled. Assume that the number of attendees of session $s_{1}$ is smaller than the number of $s_{2}$, that means $a_{s_{1}}<a_{s_{2}}$. Even though all capacity constraints might be satisfied, it could be that $s_{1}$ is scheduled to a room that has greater capacity than the room of $s_{2}$. This case is not restricted by the model formulation, as long as the capacity constraints remain feasible. From the point of view of a participant, it might be confusing why an apparently smaller session is scheduled in a large room, while another session of the same cluster is at nearly maxed out capacity. This case is supposed to be excluded.

A simple heuristic restores this property for the schedule by swapping the relevant sessions in the correct order according to their capacities or capacity demand respectively, see below.

## Example

Figure 23: Application of the swap heuristic
In the figure above, let $s_{1}, \ldots, s_{4}$ be sessions of cluster $c$ that are scheduled into rooms $r_{1}, \ldots, r_{4}$ at some time slot $t$. We assume that $a_{s_{1}} \leq \ldots \leq a_{s_{4}}$ and $u_{r_{1}} \leq \ldots \leq u_{r_{4}}$. The left figure shows the assignment that is obtained from the stream assignment, while the right side shows the allocation after the swap heuristic, where the sessions of $S_{c}$ are sorted in correct order with respect to their capacity demand.

We also tried a formulation of this restriction by means of additional linear inequalities in the stream assignment model, but the computation time increased drastically due to this implementation. Then we decided to use this simple heuristic. As the procedure swaps only between sessions of the same cluster, the objective value of the previous MIP model would also remain the same, since for each cluster no time connection or room is lost or added due to the swaps. Also no further constraints are violated.

For the input of the heuristic, we need a matrix $M$, where each row corresponds to a room $r \in R$ and each column to a time slot $t \in T$. The entries are the sessions $s_{r t} \in S$ that are scheduled in room $r$ and time slot $t$. The matrix is given from a solution of the stream assignment, where each stream was associated with a room. There are also given vectors $u$ and $a$, that contain the room capacities of every room or the number of attendees of every session respectively. The heuristic swaps the sessions within the matrix. In particular, it swaps only sessions of the same cluster at the same time slot. Possible swaps are performed for every cluster $c \in C$.

The first loop iterates over all time slots $t \in T$. For time slot $t$, the sets $S_{c}$ and $R_{c}$ are defined for every cluster $c$. Every session $s$ that is scheduled at $t$, is added to $S_{c}$, while the room $r$, where $s$ is scheduled, is added to $R_{c}$ (6-10). Next, we iterate over all clusters $c \in C$ and apply the sort function to $S_{c}$ and $R_{c}$. The sets are sorted by the number of attendees or the room capacities respectively. The method greedyAssign performs a greedy assignment of the sorted sessions $s \in S_{c}^{\prime}$ to the sorted rooms $r \in R_{c}^{\prime}$ in the order of the sorting. The assignment matrix is iteratively updated, until swaps are executed for all time slots.

The sort and greedyAssign methods, obviously, run in polynomial time, so the entire algorithm is polynomial for the given input sizes. From our observations, the algorithm

```
Algorithm 1 Cluster Swap Heuristic
Require: assignment matrix \(M\) with entries \(s_{r t} \in S, r \in R, t \in T\)
Ensure: swapped matrix \(M^{\prime}\)
    procedure ClusterSwap( \(M\) )
        \(M^{\prime} \leftarrow M\)
        for all \(t \in T\) do
            \(R_{c} \leftarrow \emptyset \quad \forall c \in C\)
            \(S_{c} \leftarrow \emptyset \quad \forall c \in C\)
            for all \(r \in R\) do
                \(s \leftarrow s_{r t}\)
                \(c \leftarrow c_{s}\)
                \(R_{c} \leftarrow\{r\}\)
                \(S_{c} \leftarrow\{s\}\)
            end for
            for all \(c \in C\) do
                \(S_{c}^{\prime} \leftarrow \operatorname{sort}\left(S_{c}, a_{s}\right)\)
                \(R_{c}^{\prime} \leftarrow \operatorname{sort}\left(R_{c}, u_{r}\right)\)
                \(M^{\prime} \leftarrow \operatorname{greedy} A \operatorname{ssign}\left(M^{\prime}, t, R_{c}^{\prime}, S_{c}^{\prime}\right)\)
            end for
        end for
    return \(M^{\prime}\)
    end procedure
```

has almost no effect on the computation time.

## 7 Room assignment

This section deals with the last optimization step, the room assignment. From the solutions of the previous optimization models, we obtained the time slot and the stream of every session. That means we know how the sequences of sessions that appear in the same room, look like. Finally, each stream must be assigned to room that is available for the conference. Walking distances between streams with similar content should be minimized.

Regarding this as a separate subproblem, is definitely important for large scale conferences. The sessions of the ISMP 2012 occupied 40 different rooms that were distributed over two different buildings and 10 floors. Since many participants change to other talks within a session, they have only five minutes to change the room until the next talk begins. Conference attendees will feel uncomfortable when they have to rush between the talks, what is caused by too long walking distances. Thus, our approach is to allocate 'similar' streams to 'nearby' rooms.

In the following we will explain the concepts of the regarded 'distance' between the rooms and the 'similarity' between two streams. Furthermore, we will discuss the associ-
ated combinatorial problem and also present a Mixed-Integer-Programming formulation to solve it.

### 7.1 Room distances

For every pair $(i, j)$ of rooms, we define a value $\delta_{i j}$ that represents the distance between the rooms $i$ and $j$. One possibility is to make use of door-to-door distances, using coordinates of every room. A distance measure, for example Euclidean- or Manhattandistances, can be used for this. In particular, the term 'distances' does not only have to refer to pure distances. It could also indicate a degree of displeasure to change between two rooms. For instance, penalty values for going up a stairway, taking the elevator, the crossing of a street, changing the building or taking crowded corridors can be mentioned here. A good choice of the distance values depends on the specific room map for the conference.

At ISMP 2012 we used 3 -dimensional room coordinates $\left(x_{r}, y_{r}, z_{r}\right)$, where $x_{r}, y_{r}$ denote the coordinates in the plane and $z_{r}$ the floor of a room $r$. We also introduced penalty values $\lambda_{1}, \lambda_{2}$ for changing the floor or the building respectively. The corridor ways and the building structure of TU-Berlin is similar to Manhattan-distances, so the distances $\delta_{i j}$ between two rooms $(i, j)$ were defined as:

$$
\delta_{i j}= \begin{cases}\left|x_{i}-x_{j}\right|+\left|y_{i}-y_{j}\right|+\lambda_{1}\left|z_{i}-z_{j}\right|, & \text { if }(i, j) \text { in the same building } \\ \left|x_{i}-x_{j}\right|+\left|y_{i}-y_{j}\right|+\lambda_{1}\left|z_{i}+z_{j}\right|+\lambda_{2}, & \text { otherwise }\end{cases}
$$

Note that a participant has to overcome the $z$-coordinate twice when he changes the building. This is an idea on how those values can be determined. Naturally, we will restrict to $\delta_{i j} \geq 0$.

### 7.2 Similarity values

Regarding room changes, streams with similar content should be assigned to nearby rooms. Therefore, we define a similarity value for each pair of streams which depends on the included sessions. We assume that participants either choose sessions with the same or a similar cluster for a room change. Thus, we will define a similarity value between clusters first, until we construct a similarity value between streams on the basis of that definition.

### 7.2.1 Cluster similarity

We consider two clusters as 'similar', if there are overlaps in the topic or the content. The higher the overlap the higher is the similarity. For the definition it is useful to create superordinate attributes that give an idea of the possible contents. From the number of matching attributes between two clusters, we calculate a similarity coefficient. Usually, similarity coefficients in a range from $[0,1]$ are used.

For example, let $A$ and $B$ denote the set of attributes that belong to two clusters. Often used similarity coefficients are the following, see [15]:

## Jaccard index:

$$
J(A, B):=\frac{|A \cap B|}{|A \cup B|}
$$

## Dice-Sørensen index:

$$
D S(A, B):=\frac{2|A \cap B|}{|A|+|B|}
$$

Tversky index: coefficients $\alpha, \beta \geq 0$ :

$$
T(A, B, \alpha, \beta):=\frac{|A \cap B|}{|A \cap B|+\alpha|A-B|+\beta|B-A|}
$$

Note that $T(A, B, 0.5,0.5)=D S(A, B)$. At ISMP we referred to the following tags or attributes respectively: Theory, Computation, Application, Discrete, Nonlinear, Stochastic. For each cluster it was decided whether it matches one of these attributes or not.

## Example

| attribute/set | $A$ | $B$ | $A \cap B$ | $A \cup B$ | $A-B$ | $B-A$ |
| :--- | :---: | :---: | :---: | :---: | :---: | :---: |
| Theory | 1 | 1 | 1 | 1 | 0 | 0 |
| Computation | 1 | 1 | 1 | 1 | 0 | 0 |
| Application | 0 | 1 | 0 | 1 | 0 | 1 |
| Discrete | 1 | 0 | 0 | 1 | 1 | 0 |
| Nonlinear | 0 | 1 | 0 | 1 | 0 | 1 |
| Stochastic | 0 | 0 | 0 | 0 | 0 | 0 |
| $\sum$ | 3 | 4 | 2 | 5 | 1 | 2 |

The table shows the set of attributes $A$ or $B$ that correspond to two exemplary clusters. It show whether it matches one of these attributes $(=1)$ or not $(=0)$. From the previous definitions, the similarity coefficients for this example would be:

$$
\begin{aligned}
& J(A, B)=0.4 \\
& D S(A, B)=0.571 \\
& T(A, B, 1,0.5)=0.5
\end{aligned}
$$

Modifications with fractional values in the table could be used as well. Again, this is just an approach, how similarities between clusters could be defined. This is a fast and easy method to implement in practice. Dependent on the choice of the attributes, it also yields a good representation of the similarities between two clusters. For the upcoming procedure we denote the similarity value for a cluster pair $\left(c, c^{\prime}\right)$ by $\beta_{c c^{\prime}}$. We further restrict to $\beta_{c c^{\prime}} \geq 0$.

### 7.2.2 Stream similarity

In this section, we define the similarity values between each pair of streams. From the definition, each stream is a sequence of sessions $\left(s_{1}, \ldots, s_{T}\right)$ that occur successively in the same room. Let $i$ and $j$ denote two streams with sessions $s_{i t}$ and $s_{j t}$ at time slot $t$. Furthermore, let $c_{i t}$ denote the cluster of session $s_{i t}$. The main goal is to minimize the walking distances between parallel sessions. Secondly, we also want sessions at successive time slots to take place in nearby rooms. Therefore, we have to consider all relations between sessions at parallel and successive time slots. Below there is shown a figure with the regarded relations.

Figure 24: Room changing relations between two streams
Note that we do not need to consider the relations between different days (where $d_{t} \neq d_{t+1}$ ). Let $T^{\prime}=T-\max (T)$, then the similarity value $\sigma_{i j}$ between streams $i$ and $j$, is defined as weighted sum over the cluster similarities $\beta_{c c^{\prime}}$ of the regarded relations:

$$
\sigma_{i j}=\sum_{t \in T^{\prime}} w_{1}(\underbrace{\left.\beta_{c_{i t} c_{j t}}+\beta_{c_{j t} c_{i t}}\right)}_{\text {parallel relations }}+\sum_{t \in T^{\prime}: d_{t}=d_{t+1}} w_{2} \underbrace{\left(\beta_{c_{i t} c_{j t+1}}+\beta_{c_{i t+1} c_{j t}}\right)}_{\text {relations at successive time slots }}
$$

The additional weight coefficients $w_{1}, w_{2} \geq 0$ are applied to distinguish between the importance of parallel and successive relations. Parallel room changes appear more important, because the breaks in parallel sessions are much shorter. Our scenarios use weights of $w_{1}=1$ and $w_{2}=0.5$.

### 7.3 The room assignment problem

Finally, the streams are assigned to rooms such that the distance between similar streams is minimized. We denote this problem as the Room Assignment Problem (RAP). In the next sections we introduce the associated combinatorial problem of the RAP. Furthermore, we give a Mixed-Integer-Programming formulation of the RAP and discuss the complexity of that problem. In the last subsection we present an approach to reduce the problem size to compute instances that are comparable to the ISMP.

### 7.3.1 Room assignment problem and MIP formulation

Let $I$ denote the set of streams that is obtained by a solution of the stream assignment. The set of sessions that are contained in stream $i \in I$, is defined by $S_{i}$. We denote
$a_{i}^{\max }=\max _{s \in S_{i}}\left(a_{s}\right)$ as the largest session in stream $i$. An assignment of stream $i$ to room $r$ is feasible, if and only if $a_{i}^{m a x} \leq u_{r}$ because each session of the stream must comply with the room capacity. To deduce a combinatorial model, every feasible assignment $(i, r)$ of a stream $i$ to room $r$ is modeled as separate vertex in a vertex set $V$, which is given by:

$$
V=\left\{(i, r) \mid i \in I, r \in R, a_{i}^{\max } \leq u_{r}\right\}
$$

Between each pair $\left(i_{1}, r_{1}\right),\left(i_{2}, r_{2}\right) \in V$ of assignments, we have to consider the distance $\delta_{r_{1} r_{2}}$ and the similarity $\sigma_{i_{1} i_{2}}$ of the rooms and streams respectively. Therefore, the relations between two assignments $u, v \in V$ are modeled as undirected edges. Since each stream is allocated exactly once, as well as each room is occupied by one stream, the edges between assignments of equal streams or rooms are excluded. The edge set $E$ reads as follows:

$$
E=\left\{\left(i_{1}, r_{1}, i_{2}, r_{2}\right) \mid\left(i_{1}, r_{1}\right),\left(i_{2}, r_{2}\right) \in V, i_{1}<i_{2}, r_{1} \neq r_{2}\right\}
$$

The induced undirected graph is defined as $G=(V, E)$.

Definition 21. Let $G=(V, E)$ be an undirected graph with vertex set $V$ and edge set $E$. We say $G$ is complete, if each pair of vertices in $V$ is adjacent. A complete subgraph of $G$ is called a clique. Furthermore, a clique with the largest possible number of vertices is called a maximum clique.

Definition 22. Given a graph $G=(V, E)$, a stable set $\mathcal{S} \subseteq V$ is a subset of vertices, where each pair of vertices in $\mathcal{S}$ is non-adjacent.

The graph $G$ of the room assignment problem has a special structure. Let $V_{i}=$ $\{(i, r) \mid(i, r) \in V\}$ and $V_{r}=\{(i, r) \mid(i, r) \in V\}$ be the set of assignments that correspond to a stream $i$ or room $r$ respectively. By the definition of the edge set, each $V_{i}$ and $V_{r}$ is a stable set, because no edge occurs between equal streams and rooms. Consequently, for $I$ and $R$, there exists a decomposition of $G$ into disjoint stable sets with $V=\bigcup_{i \in I}\left\{V_{i}\right\}$ and $V=\bigcup_{r \in R}\left\{V_{r}\right\}$, since each vertex is covered by one of these sets.

The problem of the room assignment consists in finding a selection of assignments (vertices) such that each stream and each room belongs to exactly one assignment. Whenever two assignments are selected, the edge between them must be selected as well. Assume that each edge has a certain cost, depending on the distance and the similarity values between the incident assignments, and let $b=|I|=|R|$ denote the number of streams or rooms respectively. We can describe the problem as follows:

Find a clique of size $b$ in $G$ such that the total edge cost of the clique is minimal.

Figure 25: Two distinct decompositions of $G$ with $|I|=|R|=3$ into stable sets and the selected clique

Note that a feasible solution of the stream assignment implies the existence of a clique of size $b$ because room capacities were considered explicitly. In addition, the problem description already excludes multiple assignments of streams and rooms. From the definition of $E$, there is a partition into $b$ stable sets $V_{i}$ or $V_{r}$ respectively. Since there is one stable set that covers all vertices of a stream or room respectively, and a clique must be complete, multiple assignments of rooms or streams are excluded. Moreover, each of the partitions contains exactly $b$ stable sets, therefore, one vertex from each stable set must be selected. In particular, $b$ is also the size of the largest clique in $G$ because an additional vertex would necessarily contain a stream and room that is already among the $b$ selected vertices. Thus, each clique of size $b$ is also a maximum clique.

## Mixed Integer Program

We define the binary variables $x_{v}$ to be 1 , if an assignment $v=(i, r) \in V$ of a stream $i$ to room $r$ is selected, and 0 otherwise. Furthermore, the binary variable $y_{u v}$ is 1 , if the edge $(u, v)$ between two assignments $u, v \in V$ is selected. We denote the cost of each edge $(u, v)=\left(i_{1}, r_{1}, i_{2}, r_{2}\right)$ by $\sigma_{i_{1} i_{2}} \delta_{r_{1} r_{2}}=\lambda_{u v}$. Here, $\sigma_{i j}$ is the similarity value between streams $i_{1}, i_{2}$ and $\delta_{r_{1} r_{2}}$ the distance value between rooms $r_{1}, r_{2}$, as introduced in the previous sections. The total cost of the selected edges is minimized. Therefore, it is more valuable to choose greater distances for lower similarities and shorter distances for higher similarity values. The Mixed-Integer-Program reads as follows:

$$
\begin{array}{lll}
\min & \sum_{(u, v) \in E} \lambda_{u v} y_{u v} & \\
\text { s.t. } & \sum_{v \in V} x_{v}=b & \\
& \sum_{v \in V_{i}} x_{v} \leq 1 & \forall i \in I \\
& \sum_{v \in V_{r}} x_{v} \leq 1 & \forall r \in R \\
& y_{u v}-x_{u} \leq 0 & \forall(u, v) \in E \\
& y_{u v}-x_{v} \leq 0 & \forall(u, v) \in E \\
& x_{u}+x_{v}-y_{u v} \leq 1 & \forall(u, v) \in E \\
& (b-1) x_{v}=\sum_{u \in \delta(v)} y_{u v} & \forall v \in V  \tag{7}\\
& \\
& x_{v} \in\{0,1\} & \forall v \in V \\
y_{u v} \in\{0,1\} & \forall(u, v) \in E
\end{array}
$$

Note that the integrality condition for $y_{u v}$ can be relaxed to $0 \leq y_{u v} \leq 1$ for all $(u, v) \in E$. The objective function minimizes the total cost, which is the sum over the cost of all selected edges. Inequality (1) says, that exactly $b$ vertices must be chosen. It must also be ensured that at most one stream and room is chosen from the selected vertices that are given by constraints (2) and (3). The next inequalities (4) and (5) indicate, that whenever an edge between two assignments $u$ and $v$ is selected, then also $u$ and $v$ must be selected. Similarly, constraint (6) yields that whenever two assignments $u$ and $v$ are chosen, then also the edge $(u, v)$ must be selected. The inequalities of (7) state that whenever an assignment $v$ is chosen, then there must exist $b-1$ incident edges to $v$ because the selected clique has size $b$.

As a special remark we have to mention that inequalities (2) and (3) are redundant in this MIP formulation. Summing up (7), together with (4) yields

$$
b-1=(b-1) \sum_{v \in V_{i}} x_{v}=\sum_{v \in V_{i}} \sum_{u \in \delta(v)} y_{u v} \leq \sum_{v \in V_{i}} \sum_{u \in \delta(v)} x_{u}
$$

If we substract this inequality from (1), we get $\sum_{u \in V_{i}} x_{u} \leq 1$, that is (2). Constraint (3) is obtained analogous. These inequalities will be needed later, so they are already introduced with this model.

### 7.3.2 Previous work and related problems

Since the room assignment problem is quite special for itself, we generalize this problem. The considered problem is to find a clique of size $b$ with minimal edge weight. We could also relax this formulation to find a clique of size $\geq b$ that has minimal edge weight
because, as mentioned, the largest clique in the room assignment graph already has size $b$. We will also refer to complete graphs for the generalization. Therefore, we reformulate the problem to: Given an undirected complete graph $G=(V, E)$ with edge cost $\lambda_{e}$, find $a$ clique of size $\geq b$ that has minimal edge cost.

The problem of finding minimal edge weighted cliques with minimum clique size requirement was rather studied for one cliques only, but for clique partitionings, see Mitchell and Ji [23]. We can also mention the closely related Maximum Edge Weighted Clique Problem (MEWCP) that was extensively studied in the recent years, see [5],[6],[7] and [19]. The problem can be stated as follows: given an undirected complete graph, find a clique of size $\leq b$ that has maximal edge weight.

It is possible to reduce the RAP to MEWCP by changing the edge weights to $\lambda_{e}^{\prime}=$ $\Lambda-\lambda_{e}>0$, where $\Lambda$ is a large constant. If we solve the induced MEWCP, we would also obtain the maximal clique of size $b$, as the considered edge weights are strictly positive. If $\mathcal{C}$ would be such an optimal clique, then

$$
\begin{array}{ll} 
& \sum_{e \in E(\mathcal{C})} \lambda_{e}^{\prime}=\sum_{e \in E(\mathcal{C})}\left(\Lambda-\lambda_{e}\right)=b(b-1) / 2 \cdot \Lambda-\sum_{e \in E(\mathcal{C})} \lambda_{e} \text { is maximal } \\
\Leftrightarrow & \sum_{e \in E(\mathcal{C})} \lambda_{e} \text { is minimal }
\end{array}
$$

In particular, every valid inequality of the reduced MEWCP problem is also valid for the original RAP, as no possible clique is excluded.

However, the MEWCP is $\mathcal{N} \mathcal{P}$-hard, as the Maximum Clique Problem (MCP) emerges as a special case, that was also shown to be $\mathcal{N} \mathcal{P}$-hard. The MCP is to find a clique in a given graph that has maximum cardinality.

In contrast to the general MCP, the problem of finding a maximum clique in the graph of the RAP is easy to obtain, since a maximum clique represents a feasible assignment of streams to rooms. That means, finding a maximum clique in the RAP graph corresponds to an assignment problem what can be computed in polynomial time. But the additional consideration of edge weights and the lower bound on the clique size makes this problem more difficult to solve.

A more generalized option to regard the MEWCP is to consider the so-called Boolean Quadric Polytope, that describes the induced integer polytope of the general MEWCP formulation without clique size requirement. Studies on this polytopal structure have been made in [18] and [20].

### 7.3.3 Improving the computation time of the RAP

From our computational experience, the room assignment problem is very hard to solve. For our problem instances the computation time exceeds the limit that we consider to be useful for practical implementation. If all edges between all feasible assignments would be considered, then the problem becomes too large to solve. Our approach is to reduce the problem size to make progress, also with hard instances.

Again, the main idea is to delete edges of the underlying graph $G$ to a moderate number. Especially, we delete edges that we do not consider as 'important' for our problem. Every selected edge $(u, v)=\left(i, r, j, r^{\prime}\right)$ between assignments $u=(i, r)$ and
$v=\left(j, r^{\prime}\right)$ contributes to the objective function with cost $\lambda_{u v}=\lambda_{i r j r^{\prime}}=\sigma_{i j} \delta_{r r^{\prime}}$. The first observation that we make is that we can eliminate edges with $\sigma_{u v}=0$, because they will not even affect the objective value, if we would consider them or not. In general this is the case, if the similarity value $\sigma_{i j}$ between streams $i$ and $j$ is equal to zero, that means both streams have nothing in common with respect to their content. Consequently our approach is to eliminate edges that do not satisfy a certain value of similarity. As we are focusing on the assignment of similar streams to nearby rooms, this seems to be an useful approach. Therefore, let the parameter $\sigma$ define a lower bound on the similarity values up to which edges are considered in the model. We redefine the edge set as follows:

$$
E^{\prime}=\left\{\left(i, r, j, r^{\prime}\right) \mid(i, r),\left(j, r^{\prime}\right) \in V, i<j, r \neq r^{\prime}, \sigma_{i j} \geq \sigma\right\} \subseteq E
$$

The new graph $G^{\prime}=\left(V, E^{\prime}\right)$ consists of the same assignments $v \in V$, but with reduced edge set $E^{\prime}$. All variables $y_{u v}=y_{i r j r^{\prime}}$ with $\sigma_{i j}<\sigma$ are eliminated, what reduces the problem size. The relaxed optimization model of RAP is applied to the sparse graph $G^{\prime}$.

Remark 23. The elimination of edges due to $\sigma$ will violate the clique structure in general. That means we do not know whether each vertex $v$ has exactly $b-1$ incident edges in $E^{\prime}$. As we still want to select $b$ vertices, constraint (5) is not valid for $G^{\prime}$ and must be deleted from the model formulation. Every other inequality is still valid for $G^{\prime}$.

In particular, inequalities (2) and (3) are not redundant anymore due to this relaxation. In contrast, the deleted constraints (5) were 'good' inequalities and contributed to a good performance with respect to the computation time. We introduce valid inequalities that are similar to the deleted ones. For every assignment $v \in V$ we define $b_{v}=b_{i r}=\left|\left\{j \mid j \in I \backslash\{i\}, \sigma_{i j} \geq \sigma\right\}\right|$. In this formulation, $b_{v}$ is the number of adjacent assignments of vertex $v$ in $E^{\prime}$. Then the following inequalities are valid for the reduced model and replace inequalities (5) of the previous model:

$$
b_{v} x_{v} \leq \sum_{(u, v) \in E^{\prime}} y_{u v} \quad \forall v \in V
$$

## 8 Conclusion

In this thesis we provide a framework to compute conference schedules that respect a wide sets of constraints. We also introduced an approach to the robust optimization of the conference schedule, which relates to the uncertain number of attendees and the compliance with room capacities. We gained new insights into the combinatorial structures of the problems that occur during the planning of a conference.

In practice, the optimization models contributed significantly to the creation of a conference schedule that was used at ISMP 2012. Especially, the compliance with hundreds of individual scheduling requests was a great challenge. The computed conference schedules, see 'computational results', look appropriate to be used at real conferences. They provide us with the information, if the room capacities will be sufficient to accommodate all conference participants. In this context, Mixed-Integer-Programming yields a perfect application to solve the difficulties of conference scheduling.

But the model has also some weaknesses concerning the regarded problem data. The approach of computing a robust schedule highly depends on the used attractivity coefficients $\alpha_{s}$ for each session. These coefficients were determined due to attractivity indicators. A remaining problem is to decide whether the used attractivity indicators yield a good representation of an average attendee behavior. That means we actually do not know which sessions are selected by a particular attendee. From our experience at ISMP 2012, the main attractivity indicator for a session is the popularity of the speaker, since famous speakers will generally have a great audience. It will be important for future conferences to obtain this particular attractivity information for each session. It would also be helpful to integrate insider knowledge for a more realistic estimation, because not every speaker must be known by the organizers.

For further research on this topic, it would also be interesting if there are efficient methods that produce a schedule without the distinction of a time- and room assignment. As we considered mainly MIP models for the different subproblems, it would be interesting to develop an algorithmic approach for that problem. Moreover, it would be fascinating to deal with the question, if there is a schedule that can optimally satisfy the personal session preferences of every participant, when this information would be known in advance. This could also be regarded from a game theoretic perspective. The leads to the individualization of the schedule that respects individual preferences in a best possible way.

Special thanks to Prof. Dr. Ralf Borndörfer for his helpfulness and patience for this thesis.

## 9 Computational results

All presented results were computed on a Intel Core 2 Extreme X9650 3.00GHz with Gurobi Optimizer version 5.5.0.

### 9.1 Combination of Talks to Sessions

- random similarites $\sigma_{k l} \in[0,1]$
- weight coefficient $\lambda=0.75$ for both models
- $D=3, d_{k}=1 \quad \forall k \in K$
- $|K|$ denotes the number of talks
- $|S|$ denotes the number of computed sessions
- $\sigma$ is the lower bound on the considered similarity relations, that means only edges with $\sigma_{k l} \geq \sigma$ are in the problem graph (clique partitioning only)
- $|E|$ is the number of used edges in the underlying problem graph (inclusive reduction)
- all instances were computed with a constant time limit of 600 seconds
- both models were tested for the same instances, see Section 4.2 'computational experience'
- instance with $|K|=1740$ and max. $|S|=630$ refers to the ISMP proportion

### 9.3 ISMP problem instance

The ISMP 2012 problem instance was computed with the following parameters:

- 595 sessions from 24 different clusters
- 5 days, each with 3 time slots $\Rightarrow 15$ time slots
- 42 rooms
- 116 interval requests
- 45 no overlap requests
- 85 hard precedence requests
- $\epsilon=0.05$ (robustness approximation factor)
- room assignment: consider similarities $\sigma_{i j} \geq \sigma=0.5 \cdot \max _{(i, j) \in E}\left(\sigma_{i j}\right)$

| Cluster list | \# sessions |
| :--- | :---: |
| Approximation and Online Algorithms | 16 |
| Combinatorial Optimization | 85 |
| Complementarity and Variational Inequalities | 20 |
| Conic Programming | 30 |
| Constraint Programming | 10 |
| Derivative-free and Simulation-based Optimization | 11 |

| PDE-constrained Optimization | 21 |
| Robust Optimization | 16 |
| Sparse Optimization and compressed Sensing | 14 |
| Stochastic Optimization | 37 |
| Telecommunications and Networks | 20 |
| Variational Analysis | 30 |

Multiple attendances of single persons (sessions of each person must not overlap!)

| \# sessions to be present | 2 | 3 | 4 | 5 | 6 | 7 | 8 |
| :--- | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| \# persons | 152 | 28 | 8 | 4 | 2 | 1 | 1 |

The problem instance was computed for different numbers of attendees $n$ to simulate the effect of hard capacity restrictions on the final schedule. We used a constant time limit of 600 seconds for each model. The robust view shows the probabilities that the room capacities will be sufficient (not be exceeded) for each assignment. This is calculated on the basis of the probabilities that we have introduced in Definition 15.
9.3.1 Instance 1: $n=500$

- $\gamma_{s}=0.95$ (certainty value)

## Solution process

| Model | \# variables | \# constraints | CPU time(s) | \%gap |
| :--- | :---: | :---: | :---: | :---: |
| Time assignment | 10,779 | 5,815 | 600 | 0.01 |
| Stream assignment | 69,974 | 91,945 | 315.76 | optimal |
| Room assignment | 47,665 | 138,926 | 395.4 | optimal |
