Safe reduction rules for weighted treewidth

ZIB-Report 02–49 (December 2002)

Safe reduction rules for weighted treewidth*

Frank van den Eijkhof† Hans L. Bodlaender‡
Arie M.C.A. Koster§

Abstract

Several sets of reductions rules are known for preprocessing a graph when computing its treewidth. In this paper, we give reduction rules for a weighted variant of treewidth, motivated by the analysis of algorithms for probabilistic networks. We present two general reduction rules that are safe for weighted treewidth. They generalise many of the existing reduction rules for treewidth. Experimental results show that these reduction rules can significantly reduce the problem size for several instances of real-life probabilistic networks.

1 Introduction

For many graph problems, it is useful and important to find a tree decomposition of minimal width (called treewidth) [4, 11, 13]. Often these problems can be solved in linear or polynomial time when a tree decomposition of bounded width is known.

The problem of finding a tree decomposition with minimum width is NP-hard [1], and approximating treewidth is also NP-hard [10]. In [6] it was shown that preprocessing techniques can help reducing the size of instances of these problems. A set of reduction rules is given that can be used to preprocess a graph for the computation of its treewidth. Each of these rules reduces the number of vertices of the graph. Rules for which a tree decomposition for the reduced graph with minimum treewidth can easily be extended to a tree decomposition for the original graph that also has minimum treewidth are called safe. To allow more safe rules, a variable *low* is maintained that invariantly is a lower bound on the treewidth of the graph. A reduction rule is now called *safe*, if and only if the maximum of *low* and the treewidth of the graph is not changed. More results on reduction algorithms for graphs of bounded treewidth can be found in [2, 8].

In this paper, we generalise the results of [6] to a weighted variant of treewidth. The problem is motivated from the area of probabilistic networks, but it is also useful for combinatorial optimisation problems. Several modern decision support systems have *probabilistic networks* as underlying technology [15]. These networks model dependencies and independencies between statistical variables using a directed acyclic graph. For each statistical variable, represented by a vertex in the graph, a probabilistic function is defined. The most important problem to solve on these networks is *probabilistic inference*, which computes the probability distribution of a variable given a value-assignment to other variables. The most efficient algorithm currently used for probabilistic inference is based upon the use of a tree decomposition of the so-called moralised graph of the network, since this graph appears to have small treewidth for many probabilistic networks that model real-life situations. We refer to e.g., [9, 13] for details.

A tree decomposition consists of a number of 'bags', organised in a tree. (For the precise definition, see Section 2.) The treewidth is one smaller than the maximum size of a bag. The time the algorithm from [9, 13] takes to process one bag is proportional to the product over the variables represented by vertices in the bag of the number of different values they can attain. So, e.g., if we have a probabilistic network with all variables having the same number c of values (for instance, $c = 2$ for binary variables), then the time to execute the algorithm based on a tree decomposition with n bags and of width k becomes bounded by $O(c^k \cdot n)$. In such a case, one may want to find a tree decomposition of minimum treewidth to be used by the probabilistic inference algorithm. However, the statistical variables in a probabilistic network may have different numbers of values, and thus a tree decomposition with minimum treewidth may not be optimal for this algorithm. Instead of treewidth, we therefore consider the weighted treewidth

problem, where we try to find tree decompositions such that the maximum over all bags of the product of the weights of the vertices in the bag is as small as possible. We notate the weight of vertex v by $w(v)$; this is the finite number of values the variable associated with v can attain. The weighted treewidth expresses the maximum product of weights of the bags in a tree decomposition (note that when all vertices have weight c, the treewidth of a graph is one less than the logarithm (with base c) of the weighted treewidth).

When preprocessing a graph, regardless we consider weighted or unweighted treewidth, we repeatedly apply safe reduction rules from some set, until no more rules from the set can be applied. After construction of a tree decomposition for the remaining graph, undoing the reductions in reverse order gives us a tree decomposition for the original graph. In case the remaining graph is empty, the optimal weighted treewidth is computed this way. In case the remaining graph is not empty, whether the optimal weighted treewidth is obtained depends on the technique used to produce a tree decomposition for the reduced graph. An exact, but possibly computationally expensive algorithm (like integer linear programming) guarantees a tree decomposition with optimal weighted width for the original graph. By using heuristic algorithm(s) only an approximation of the weighted treewidth is obtained. This approximation becomes exact, although no exact algorithm is used, when the weighted width computed for the reduced graph is at most the value *low*.

In Section 3, we present two rules for preprocessing weighted treewidth. The first is the Simplicial rule, which is a rather straightforward generalisation of the non-weighted case. It removes a simplicial vertex, which is a vertex for which all neighbours form a clique, and updates a variable *low* representing the lower bound for the weighted treewidth of the original graph. The second rule comprises many possible reduction rules. It is called the *Contraction Reduction rule*. For this rule we try to generate a clique that separates some single vertices from the rest of the graph using *contraction* of edges. Besides the safeness for this rule, we show that the detection whether the contraction reduction rule can be applied is in general NP-complete. In Section 4, we consider several special cases of the Contraction Reduction rule that can be identified in polynomial time. Unweighted variants of these instances, specially the Almost Simplicial, Buddy and (Extended) Cube rules have been introduced and proven safe for unweighted treewidth previously in [4, 6]. We thus have generalised these rules to the weighted case. In addition, we obtain new rules which are safe for weighted treewidth. The Buddies rule generalises the Buddy rule and is an example of such a new rule.

As for the unweighted case, the contraction reduction rule bases on a variable *low* that invariantly is a lower bound on the weighted treewidth.

The higher *low* is, the more effective the rule can be. To increase *low* in practice, we discuss in Section 5 lower bounds for weighted treewidth. Several experiments conducted by applying the reduction rules on 23 real-life probabilistic networks and lower bounds are presented in Section 6. Our experiments reveal that for several networks a decomposition with minimal weighted width can be found, while most remaining networks are reduced significantly. Some concluding remarks close the paper.

2 Definitions and preliminaries

In this paper, we assume that graphs are undirected, simple, and have a weight function $w : V \to \mathbf{N}^+$. We use the notation $G = (V, E, w)$.

We assume familiarity with standard graph notions, like independent set, clique, etc.

Let $G = (V, E, w)$ be a graph. With $\bar{G}$ we define the complement of G. The set of neighbours of a vertex v is denoted $N(v)$. Note that we assume that $v \notin N(v)$. The *degree* of a vertex is denoted as $deg(v) = |N(v)|$. A vertex $v \in V$ is *simplicial* when $N(v)$ induces a clique. A *subgraph* $H(G)$ of G is a graph $H = (V', E', w[V'])$ with $V' \subseteq V$, $E' \subseteq (V' \times V') \cap E$, and $w[V'] : V' \to \mathbf{N}^+$ a function that assigns for every vertex $v \in V'$ the value $w(v)$ to $w[V'](v)$. For a set of vertices $W \subseteq V$, the *subgraph induced by* W is the subgraph $G[W] = (W, (W \times W) \cap E, w[W])$. For the sets of vertices $W, X \subset V$, W and X disjoint, the set X *separates* W when every path between a vertex in W and a vertex in $V \backslash (W \cup X)$ uses a vertex in X.

Let $G = (V, E, w)$ be a graph. The weight of a set of vertices $S \subseteq V$ is $w(S) = \prod_{v \in S} w(v)$. The *neighbourhood weight* or $nw_G(v)$ of a vertex $v \in V$ is $nw_G(v) = w(N(v) \cup \{v\})$. When G is clear from the contest, we write $nw(v)$.

A *tree decomposition* of a graph $G = (V, E)$, or a weighted graph $G = (V, E, w)$, is a pair $(\{X_i | i \in I\}, T = (I, F))$ with T a tree and for every $i \in I$ a *bag* $X_i \subseteq V$, such that for each vertex $v \in V$ there exists a bag with $v \in X_i$, for each edge $\{v, u\} \in E$ there exists a bag with $v, u \in X_i$, and for each vertex $v \in V$ the induced graph $T[S_v]$, with $S_v = \{i \in I | v \in X_i\}$, is a tree.

The *width* of a tree decomposition $(\{X_i | i \in I\}, T = (I, F))$ of a (weighted) graph $G = (V, E, w)$ equals $\max_{i \in I} |X_i| - 1$; the *treewidth* of a graph G, denoted $\tau(G)$ is the minimum width over all tree decompositions of G. Similar the *weighted width* equals $\max_{i \in I} w(X_i)$ (without minus 1!) and the *weighted treewidth* of a graph G, denoted $\tau_w(G)$, is the minimum weighted width over all tree decompositions of G.

Let $G = (V, E, w)$ be a graph. A *contraction* of an edge $\{v, u\} \in E$ with

$w(v) \leq w(u)$ makes v adjacent to $(N(v) \cup N(u))\backslash\{v\}$, and removes vertex u and edge $\{v, u\}$. Rephrased more intuitively, an edge is contracted to the incident vertex that has the smallest weight.

A *minor* of a graph G is a graph G' that is obtained from G by a sequence of zero or more vertex removals, edge removals, and/or edge contractions.

Lemma 1 *Let G' be a minor of G. Then $\tau_w(G') \leq \tau_w(G)$.*

Proof. (This proof is similar to that for the unweighted case, see e.g. [5, Lemma 16].) Let $(\{X_i | i \in I\}, T = (I, F))$ be a tree decomposition of $G = (V, E)$ of optimal width. If G' is obtained from G by removing an edge $e \in E$, then $(\{X_i | i \in I\}, T)$ is also a tree decomposition of G. If G' is obtained from G by removing a vertex $v \in V$, then $(\{X_i - \{v\} | i \in I\}, T)$ is a tree decomposition of G. If G' is obtained from G by contracting the edge $\{x, y\} \in E$ to vertex x with $w(x) \leq w(y)$, then $(\{X'_i | i \in I\}, T = (I, F))$ with for all $i \in I$, $X'_i = X_i$ when $y \notin X_i$ and $X'_i = X_i - \{y\} \cup \{x\}$ when $y \in X_i$, is a tree decomposition of G'. In each case, the weighted treewidth of G' is at most the treewidth of G. The result now follows by induction. □

3 General reduction rules

In this section we define two general reduction rules. Both rules concentrate upon deletion of vertices that can be separated from the graph by cliques. The first rule deletes simplicial vertices, and the second rule is based upon sets of edges that can be contracted such that they form cliques in the graph. It's unweighted version generalises some reduction rules known for (unweighted) treewidth. In the next section we discuss these special cases in the context of weighted treewidth.

When reversing a reduction, for each vertex deleted in the reduction a new bag is added containing this vertex and its neighbours. Because the neighbours form a clique in the reduced graph, the bag can be easily added to the tree decomposition. We must be able to guarantee that this bag will not increase the weighted treewidth to a value above the weighted treewidth of the original graph. Therefore we maintain a variable *low* that represents the largest lower bound we know for the weighted treewidth of the original graph.

A reduction rule is called *safe* when application of the rule changes a graph G and its associated variable low_G, into G' and its associated variable $low_{G'}$, such that $\max(low_G, \tau_w(G)) = \max(low_{G'}, \tau_w(G'))$. Safeness of a reduction rule implies that when we start with *low* having any value that is at most the weighted treewidth of the original graph, the rule does not increase the

weighted treewidth of the graph above that of the original graph. In Section 5 we discuss a heuristic for setting an initial *low*.

3.1 The Simplicial Rule

The Simplicial rule is a straightforward generalisation of the same rule of the unweighted case, and easily follows from well-understood properties of chordal graphs and tree decompositions.

> **The Simplicial rule**
> Let v be a simplicial vertex in graph $G = (V, E, w)$.
> Set low to $\max(low, nw(w))$.
> Remove v and its incident edges from G.

Theorem 2 *The Simplicial rule is safe.*

Proof. As G contains a clique of weight $nw(v)$, we know that $\tau_w(G) \geq nw(v)$. Furthermore, because $G - v$ is a minor of G, we know that $\tau_w(G) \geq \tau_w(G - v)$. Therefore, $\tau_w(G) \geq \max(nw(v), \tau_w(G - v))$.

Now let T' be a tree decomposition for $G - v$ with weighted width $k \leq \max(nw(v), \tau_w(G - v))$. We create a tree decomposition T by adding a bag X_i to T' as follows. Bag X_i consists of $N(v) \cup \{v\}$, and we connect X_i to a bag X_j in T' with $i \neq j$ and $N(v) \subseteq X_j$. Since $N(v)$ is a clique in G', X_j exists ([7, Lemma 3.1]). The weighted width of T now equals $\max(nw(v), k)$, and thus $\tau_w(G) \leq \max(nw(v), \tau_w(G-v))$, hence $\tau_w(G) = \max(nw(v), \tau_w(G-v))$. □

In Figure 1 an application of the Simplicial rule is illustrated. Solid lines represent edges, and the dotted lines connect to the remainder of the graph. The numbers represent the weights on the vertices. For this example, *low* will become at least 120.

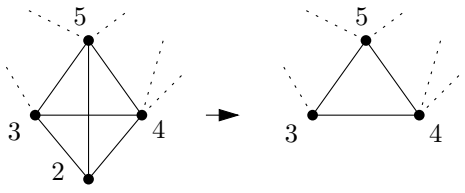

Figure 1: An instance of the *Simplicial rule*.

3.2 The Contraction Reduction Rule

Next, we introduce the general Contraction Reduction rule and show that it is safe. We also show that it is NP-complete to determine for a given graph G whether it is possible to carry out the Contraction Reduction rule in G. Fortunately, there are several special instances of the rule for which there are efficient algorithms that determine if and where the rule can be carried out in a given graph; several of these cases will be discussed in Section 4. We first define the notion of *contraction reduction*.

Definition A *contraction reduction* in a weighted graph $G = (V, E, w)$ is a 3-tuple (X, Y, S) with $X,\ Y \subset V$ disjoint non-empty sets of vertices, and $S \subseteq E$ a set of edges, with the following properties:

1. X is an independent set.
2. Each edge in S has one endpoint in X and one endpoint in Y.
3. A vertex in X is incident to exactly one edge in S.
4. For each $x \in X$, $N(x) \subseteq Y$.
5. For each $\{x, y\} \in S$, $x \in X$, $y \in Y$: $w(x) \geq w(y)$.
6. Contraction of all edges in S will turn Y into a clique.

See Figure 2 for an example of a contraction reduction; the edges in S are drawn by fat lines. An equivalent way of stating the last condition of a contraction reduction is that for every pair of vertices $y, y' \in Y$, either $y = y'$, $\{y, y'\} \in E$, or there is an $x \in X$ with $\{x, y\} \in S$ and $\{x, y'\} \in E$ or $\{x, y\} \in E$ and $\{x, y'\} \in S$. There are some special cases of contraction reductions that are 'uninteresting', e.g., when there is a simplicial vertex $x \in X$ for contraction reduction (X, Y, S). In order not to make the definition more complex, we do not explicitly forbid this case.

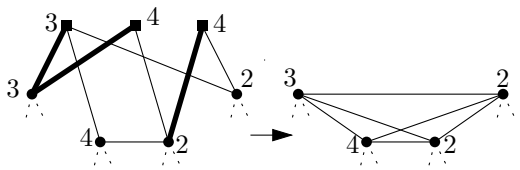

Figure 2: A contraction reduction

The Contraction Reduction rule
Let (X, Y, S) be a contraction reduction in $G = (V, E, w)$.
If $low \geq \max_{x \in X} nw(x)$,
then Remove all vertices of X from G.
Turn Y into a clique.

Next, we show the safeness of the Contraction Reduction rule.

Theorem 3 *The Contraction Reduction rule is safe.*

Proof. Let G, low be given. Suppose (X, Y, S) is a contraction reduction in G, and $low \geq \max_{x \in X} nw(x)$. Let G' be the graph, resulting from the application of the rule. Note that G' is obtained from G by contracting all edges in S, so G' is a minor of G, and hence $\tau_w(G') \leq \tau_w(G)$. Combined with the precondition $low \geq \max_{x \in X} nw(x)$, we have that $\max(low, \tau_w(G)) \geq \max(\tau_w(G'), \max_{x \in X} nw(x))$.

Now let T' be a tree decomposition of G'. We obtain T from T' by adding a bag X_x to T' for each vertex $x \in X$ as follows. Bag X_x consists of $N(x) \cup \{x\}$, and we connect X_x to a bag X_j in T' with $x \neq j$ and $N(x) \subseteq X_j$. Since $N(x) \subseteq Y$ is a clique in G', X_j exists (see [7, Lemma 3.1]).

The weighted width of T is at most the maximum of $\tau_w(T')$ and $\max_{x \in X} nw(x)$, and thus $\tau_w(G) \leq \max(\tau_w(G'), \max_{x \in X} nw(x))$. Hence, $\tau_w(G) = \max(\tau_w(G'), \max_{x \in X} nw(x))$. So $\max(\tau_w(G), low) = \max(\tau_w(G'), low)$. □

Note that the contraction reduction in Figure 2 is safe when $low \geq 72$. As a byproduct of the proof of Theorem 3, we have a method to 'undo' the rules: if we have a tree decomposition of the reduced graph G' of treewidth not more than that of the original input graph, then we can construct a tree decomposition of the graph just before the reduction step by applying the construction given in the proof. The resulting tree decomposition will have weighted width at most the maximum of low and $\tau_w(G)$.

Next we show that it is NP-complete to determine for a given graph G (and value low) whether it is possible to apply the Contraction Reduction rule for G.

Theorem 4 *It is NP-complete to decide if there exists a contraction reduction in a given graph $G = (V, E, w)$, even if we require that w is a constant function.*

Proof. Clearly, the problem belongs to NP. To proof that it is NP-hard, we reduce from Vertex Cover. In the Vertex Cover problem, we are given a graph $G = (V, E)$ and an integer $k \leq |V|$, and ask if there is a set of vertices $W \subseteq V$ with $|W| \leq k$, such that every edge $e \in E$ has at least one endpoint in W.

Let a graph $G = (V, E)$, and an integer k be given. Without loss of generality, assume $|V| \geq 5$ and $k \geq 3$. Let $G' = (V', E')$ be obtained from G in the following way. Suppose $V = \{v_1, v_2, \ldots, v_n\}$. We take the complement of G, add k new vertices $\{u_1, \ldots, u_k\}$ that are made adjacent to each vertex in V, and add n new vertices $z_1, \ldots, z_n$, making z_i adjacent to z_{i-1}, z_{i+1}, and v_i, with z_1 adjacent to z_n. See figure 3.

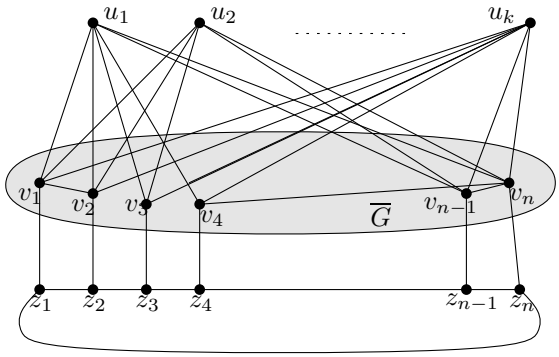

Figure 3: Graph G' in the proof of Theorem 4

We write $U = \{u_1, \ldots, u_k\}$ and $Z = \{z_1, z_2, \ldots, z_n\}$. Now, $V' = V \cup U \cup Z$, and $E' = \{\{y, z\} \mid y, z \in V,\ y \neq z,\ \{y, z\} \notin E\} \cup \{\{u_i, y\} \mid u_i \in U,\ y \in V\} \cup \{\{v_i, z_i\} \mid 1 \leq i \leq n\} \cup \{\{z_i, z_{i+1}\} \mid 1 \leq i < n\} \cup \{\{z_n, z_1\}\}$. Assume $w(y) = 2$ for all $y \in V'$.

We now claim that G has a vertex cover of size at most k, if and only if G' has a contraction reduction. As G' can be constructed in polynomial time from G, the theorem follows from this claim.

Suppose $W = \{w_1, \ldots, w_{k'}\}$ is a vertex cover of size at most k in G, $k' \leq k$. If $k' < k$, set $w_{k'+1}, \ldots, w_k$ to arbitrary vertices in V. Set $S = \{\{u_i, w_i\} \mid 1 \leq i \leq k\}$. Now, $(\{u_1, \ldots, u_k\}, V, S)$ is a contraction reduction in G'. Most conditions of contraction reduction hold by construction. We show that the contraction of edges in S turns V into a clique. Consider $y, z \in V$, $y \neq z$, either $\{y, z\} \in E'$, or otherwise, $\{y, z\} \in E$ and then $y \in W$ or $z \in W$ as W is a vertex cover. Without loss of generality, suppose $y = w_i$ for some i, $1 \leq i \leq k$. u_i is contracted to y, and as u_i is adjacent to z, the edge $\{y, z\}$ is created by the contraction. So, V forms a clique after contraction of all edges in S.

Suppose that G' has a contraction reduction (X, Y, S).

First, assume that $X \cap U \neq \emptyset$. Suppose $u_i \in X \cap U$. As $N(u_i) = V$, $V \subseteq Y$. Let W be the set of vertices in S that are endpoint of an edge in S with the other endpoint in U. It follows that $|W| \leq k$. We claim that W is a vertex cover of G. Consider a pair $y, z \in V$ with $\{y, z\} \in E$. Now $\{y, z\} \notin E'$, so the edge $\{y, z\}$ must be obtained from contracting the edges in S. As a vertex in Z is adjacent to exactly one vertex in V, $\{y, z\}$ cannot be obtained from a contraction with a vertex in Z, and hence either $y \in W$ or $z \in W$. So we have a vertex cover of G of size at most k.

Now, assume that $X \cap U = \emptyset$. This case will lead to a contradiction. Suppose $X \cap V \neq \emptyset$. As u_1 and u_2 are adjacent to each vertex in V, $\{u_1, u_2\} \subseteq Y$, and hence there must be an edge of the form $\{v_i, u_j\} \in S$, $j \in \{1, 2\}$, $1 \leq i \leq n$. Then $\{u_3, z_i\} \subseteq N(v_i) \subseteq Y$. To create the edge $\{u_3, z_i\}$ by contracting S, there must be a common neighbour of u_3 and of z_i that is contracted to u_3 or z_i, but their only common neighbour is already contracted to u_j, contradiction. So we conclude that $X \cap V = \emptyset$, and hence $X \subseteq Z$.

Suppose $z_i \in X$. To ease notation, suppose $1 < i < n$. We have that $\{z_{i-1}, z_{i+1}, v_i\} \subseteq Y$. As z_{i-1} and z_{i+1} have only z_i as common neighbour, z_i must be contracted to one of its neighbours in Z. As this argument applies to every vertex in $X \cap Z$, all endpoints of edges in S belong to Z. This yields a contradiction: either the edge $\{v_i, z_{i-1}\}$ or the edge $\{v_i, z_{i+1}\}$ is not obtained by contraction of the edges in S. This finishes the proof that G has a vertex cover of size at most k, and hence our NP-completeness proof. □

Consider the problem to decide, given a graph $G = (V, E, w)$ and a value for *low*, if G can be reduced to a smaller graph with the Contraction Reduction rule. The proof above shows that this problem is NP-complete, even in the case that $w(v) = 2$ for all vertices $v \in V$ and $low = 2^{n+1}$.

3.3 Confluence of the rules

Since several simplicial and/or contraction reduction rules can be applicable at the same time for a graph, naturally the question rises whether the order the rules are applied is of influence on the graph obtained in the end. We conjecture that this is not the case. For multiple applications of the simplicial rule this is easy to see. For the contraction reduction rule and the combination of the rules it seems to be harder to derive the result.

Conjecture 5 (Confluence of rules) *The order in which the simplicial rule and the contraction reduction rule are applied to a graph does not influence the remaining graph.*

4 Specific reduction rules

As discussed in the previous section, it is NP-complete to determine for a given graph whether the Contraction Reduction rule can be used to reduce its size. Fortunately, there are several special cases that have efficient algorithms to find out whether and where they can be applied. We first discuss these special cases which generalise known results for the unweighted case, providing sufficient conditions on the weights of vertices and the value of *low* to make these rules safe.

In [3] Arnborg and Proskurowski identified a complete set of reduction rules for (unweighted) graphs with treewidth at most three. In other words: at least one of these rules can be applied to any non-empty graph of treewidth at most three, and applying the rule will not turn a graph with treewidth at most three in one of treewidth more than three, and vice versa. Thus, the rules can be used to obtain an algorithm to recognise graphs of treewidth at most three; see also [14]. This set of rules consists of the Islet, Twig, Series, Triangle, Buddy, and (Extended) Cube rule. The Islet and Twig rule are instances of the Simplicial rule, expressing the cases that the simplicial vertex has degree 0 or 1. In [6], the Almost Simplicial rule was shown to be safe for (unweighted) treewidth. This rule generalises the Series and Triangle rule. We will show below that the Almost Simplicial rule is a special case of the Contraction Reduction rule. Also, we will show that the Buddy and (Extended) Cube rules are also special cases of the Contraction Reduction rule. In each case, this gives a proof of safeness of generalisations of these rules to the weighted case, and establishes conditions upon the weights when the rules can be carried out. Sanders [16] extended the set of rules from [3] to a much larger set of rules that is safe and complete for non-weighted graphs with treewidth at most four. However, only a subset of his reduction rules are instances of our Contraction Reduction rule; many of his rules are not reversible easily, see also [12].

We define the Almost Simplicial rule as follows.

The Almost Simplicial rule
Let u and v be vertices in graph $G = (V, E, w)$.
Suppose that v is a neighbour of u.
Suppose that $N(v)\backslash\{u\}$ forms a clique in G.
If $low \geq nw(v)$ and $w(v) \geq w(u)$,
Then Turn $N(v)$ into a clique
Remove v and its incident edges from G.

Corollary 6 *The Almost Simplicial rule is safe.*

Proof. Safeness of the Almost Simplicial rule follows from the fact that it is a special case of the Contraction Reduction rule. Let G, u, v be as in the rule given above, with $w(v) \geq w(u)$. Then $(\{v\}, N(v), \{\{v, u\}\})$ is a contraction reduction in G. The condition that $low \geq \max_{x \in X} nw(x)$ from the Contraction Reduction rule is here equivalent to $low \geq nw(v)$. Thus, by Theorem 3, the Almost Simplicial rule is safe. □

Figure 4 shows an instance of the Almost Simplicial rule; it can be carried out when $low \geq 288$. The dashed lines indicate potential edges.

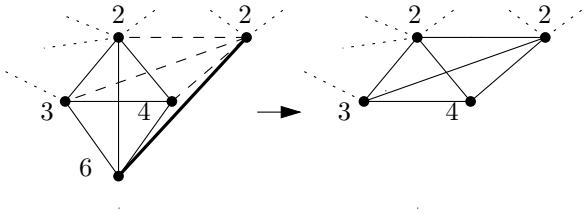

Figure 4: An instance of the *Almost Simplicial rule*.

The Series and Triangle rules are special cases of the Almost Simplicial rule. The Series rule is the case that v has degree two. So, given a vertex v of degree two, the Series rule removes v and adds an edge between its neighbours when the weight of v is at least the weight of one of its neighbours, and low is at least the product of the weights of v and the weights of its neighbours. The Triangle rule is the case that v has degree three in the Almost Simplicial rule.

We next define the Buddies rule. In the Buddies rule, we have r vertices, each with the same $r+1$ neighbours; when certain conditions on the weights and low hold, we can remove these r vertices and turn the set of $r+1$ neighbours into a clique.

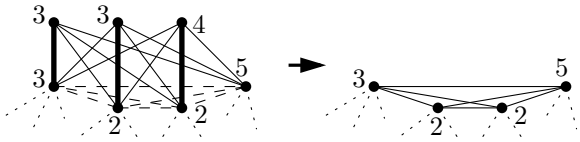

Figure 5: An instance of the *Buddies rule*.

The Buddies rule
Let r be a positive integer.
Let $X = \{x_1, \ldots, x_r\}$ be a set of r vertices in graph $G = (V, E, w)$.
Let $Y = \{y_1, \ldots, y_{r+1}\}$ be a set of $r+1$ vertices in G.

Suppose for each i, $1 \leq i \leq r$, $N(x_i) = Y$.
If $\forall_{1 \leq i \leq r} : w(x_i) \geq w(y_i)$ and $low \geq \max_{1 \leq i \leq r} nw(x_i)$
Then Turn Y into a clique
Remove the vertices in X and their incident edges from G.

From the assumptions in the Buddies rule, it follows that X and Y are disjoint sets. An example of the Buddies rule with $r = 3$ is given in Figure 5.

Corollary 7 *The Buddies rule is safe.*

Proof. The Buddies rule is a special case of the Contraction Reduction rule, and hence is safe by Theorem 3. The corresponding contraction reduction is the tuple $(\{x_1, \ldots, x_r\}, \{y_1, \ldots, y_{r+1}\}, \{\{x_i, y_i\} \mid 1 \leq i \leq r\})$: note that if we contract each x_i with y_i $(1 \leq i \leq r)$, then the set $\{y_1, \ldots, y_{r+1}\}$ turns into a clique. □

The Buddies rule given above generalises the Buddy rule, which is one of the rules in the set of rules to recognise graphs of treewidth three [3]. The Buddy rule is the special case of the Buddies rule with $r = 2$.

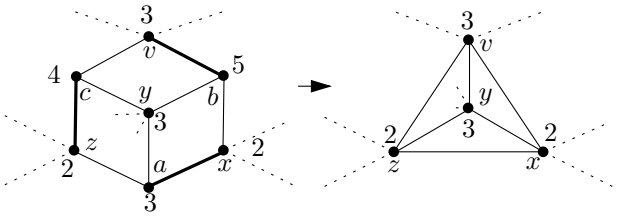

Figure 6: An instance of the *Extended Cube rule.*

The last reduction rule is taken from Arnborg and Proskurowski [3].

The Extended Cube rule
Suppose v, x, y, z, a, b, c are distinct vertices in graph $G = (V, E, w)$.
Suppose $N(a) = \{z, y, x\}$, $N(b) = \{x, y, v\}$, $N(c) = \{v, y, z\}$.
If $low \geq \max(nw(a), nw(b), nw(c))$, $w(a) \geq w(x)$, $w(b) \geq w(v)$, and $w(c) \geq w(z)$
Then Turn $\{v, w, y, z\}$ into a clique
Remove the vertices in $\{a, b, c\}$ and their incident edges from G.

Corollary 8 *The Extended Cube rule is safe.*

Proof. Observe that $(\{a, b, c\}, \{v, x, y, z\}, \{\{z, a\}, \{x, b\}, \{v, c\}\})$ is a contraction reduction. Now the result follows from Theorem 3. □

From the literature, we have a special case of the Extended Cube rule: the Cube rule. The Cube rule is obtained from the Extended Cube rule by additionally requiring that vertex y has degree three. In that case, y can be removed from the graph as well, (i.e., by application of the simplicial rule). The Cube rule can be implemented somewhat faster than the Extended Cube rule. We have not generalised the Extended Cube rule further, because our experiments for the unweighted case [6] indicate that this reduction rule seldom occurs. In Figure 6 an instance of the Extended Cube rule is given, which can be applied when $low \geq 90$.

All reduction rules mentioned are built upon existing rules. However, it is also possible to derive new reduction rules with help of Theorem 3. Consider Figure 7. Note that this subgraph can not be reduced using any of the rules mentioned in this section so far. Write $X = \{x_1, \ldots, x_5\}$, $Y = \{y_1, \ldots, y_5\}$. Suppose that for $1 \leq i \leq 5$, we have $w(x_i) \geq w(y_i)$. Then $(X, Y, \{\{x_i, y_i\} \mid 1 \leq i \leq 5\})$ is a contraction reduction. Hence, if for $1 \leq i \leq 5$, $low \geq nw(x_i)$, then turning Y into a clique and removing X and its incident edges is safe. In similar ways, several more rules can be designed, but it is unclear whether such rules would help much for the preprocessing of graphs that arise from practical applications. Our experiments described in Section 6 show that more complex rules (e.g., Buddies and (Extended) Cube rule) are seldom applied.

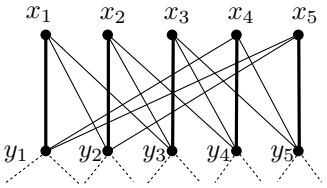

Figure 7: A contraction reduction when $w(x_i) \geq w(y_i)$ for $1 \leq i \leq 5$.

In contrast to the general contraction reduction rule, each of the rules given in this section allows a polynomial time implementation (including the time to test if a rule can be applied, and to find a possible 'spot' in the graph where the rule can be used to decrease the size of the graph.) In case of the Buddies rule, we can list for each vertex the sorted list of its neighbours, and then sort these lists lexicographically. Techniques for efficient implementations can be found e.g. in [3, 6, 14].

5 Rules to Increase the Lower Bound

When the value of the variable *low* is larger, i.e., closer to the weighted treewidth of the original graph, then the Almost Simplicial rule, Buddies rule, and Extended Cube rule, or more generally the Contraction Reduction rule, can be applied in more cases. Thus, it can be advantageous to spend time for obtaining a better lower bound on the weighted treewidth of the original graph, or of graphs obtained during preprocessing. Our experiments, reported in Section 6, support this. In this section, we discuss a method to increase the lower bound. Our lower bound heuristic is simple to implement and appears to give often good results. It builds upon Lemma 1, and the following result, which generalises a well known fact for the unweighted case.

Lemma 9 *For every graph $G = (V, E, w)$: $\tau_w(G) \geq \min_{v \in V} nw(v)$.*

Proof. Let $(\{X_i \mid i \in I\}, T = (I, F))$ be a tree decomposition of G of minimum weighted width, and a minimum size $|I|$. We claim that there is a vertex $v \in V$, and a node $i \in I$ with $v \cup N(v) \subseteq X_i$. This claim clearly holds when $|I| = 1$. Otherwise, take an arbitrary leaf node $i \in I$ from T, and suppose j is the unique neighbour of i in T. If $X_i \subseteq X_j$, then removing i from T gives a tree decomposition of G, still with minimum weighted width, but with a smaller size of $|I|$, which contradicts our assumptions. Thus, we may suppose that there is a vertex $v \in X_i$, with $v \notin X_j$. By the definition of tree decomposition, there is no $i' \neq i$ with $v \in X_{i'}$; hence, for every edge $\{v, w\}$, we have $w \in X_i$, so $v \cup N(v) \subseteq X_i$. We can conclude that there exists a vertex $v \in V$ with $\tau_w(G') \geq w(X_i) \geq nw(v)$, which proves the lemma. □

The lemma suggests the following lower bound heuristic for the weighted treewidth, called the *Maximum Minimum Neighbourhood Weight* heuristic, or MMNW for short. It repeatedly removes the vertex with the minimum neighbourhood weight until the graph is empty, and reports the maximum of these minimum neighbourhood weights seen during the process. Clearly, this number constitutes a lower bound on the weighted treewidth of the input graph since all intermediate graphs are subgraphs of G.

MMNW heuristic
Input: Graph $G = (V, E, w)$.
Output: Number ℓ with $\tau_w(G) \geq \ell$.
$\ell = 0$;
$G' = G$;
While G' is not the empty graph
Do Let v be a vertex with $nw_{G'}(v)$ minimal among all vertices in G'.

$\ell = \max\{\ell, nw_{G'}(v)\}$;
Remove v and its incident edges from G'.
Return ℓ.

A small improvement is possible to the MMNW heuristic. Instead of deleting vertices, it is also possible to contract them with a neighbour. As contracting a vertex v to a vertex x gives a vertex with weight $\min\{w(v), w(x)\}$, we refrain from contracting a vertex to a neighbour when it has only neighbours of higher weight. When the vertex v of minimum neighbourhood weight has at least one neighbour of smaller or equal weight, then we contract v to one of its neighbours; we chose the neighbour of smallest neighbourhood weight among all neighbours x with $w(x) \leq w(v)$. The resulting heuristic is called the MMNW+ heuristic.

MMNW+ heuristic
Input: Graph $G = (V, E, w)$.
Output: Number ℓ with $\tau_w(G) \geq \ell$.
$\ell = 0$;
$G' = G$;
While G' is not the empty graph
Do Let v be a vertex with $nw_{G'}(v)$ minimal among all vertices in G'.
$\ell = \max\{\ell, nw_{G'}(v)\}$;
Compute $A = \{x \mid \{v, x\} \in E \wedge w(x) \leq w(v)\}$.
If $A = \emptyset$
Then Remove v and its incident edges from G'.
Else Select the vertex x from A with $nw(x)$ minimal.
Contract the edge $\{v, x\}$ to x in G'.
(I.e., make x adjacent to all neighbours of v, and
remove v and its incident edges from G'.)
Return ℓ.

Lemma 10 *Suppose the MMNW+ heuristic, applied to G, outputs k. Then $\tau_w(G) \geq k$.*

Proof. An invariant of the algorithm is that G' is a minor of G: in each step, we either delete vertices or edges, or do an edge contraction. It follows that $\ell \leq \tau_w(G)$ is also an invariant, using Lemma 9. □

Unfortunately, it is possible that the lower bound obtained by the MMNW+ heuristic and the value of $\tau_w(G)$ differ much. Consider planar graphs with all vertices of weight two. As every planar graph has a vertex of degree at most five, the MMNW+ heuristic will never give a value larger than

2^6 on such instances, but the weighted treewidth of such planar graphs can be arbitrary large. However, in many other cases, the MMNW+ heuristic gives a reasonable lower bound for the weighted treewidth.

Other methods to increase *low* are also possible. For instance, when the graph contains a clique minor, then *low* can be set to the maximum of its current value and the weight of the clique. Such a situation would occur when a subgraph is found that fulfills the structural requirements of a contraction reduction, but not the conditions on the weights and *low*. However, lower bounds based on clique minors may be far apart from the actual treewidth (e.g., recall that planar graphs can have large treewidth but never have a clique with five vertices as a minor), and are in general intractable.

6 Computational Experiments

In this section we report on computational experiments for the described preprocessing rules. Our experiments are conducted on 23 probabilistic networks developed for real-life problems. The Alarm, BOBLO, Diabetes, Link, Munin, Oesoca, PigNet2, Pigs, VSD, and Wilson networks are taken from medical applications; several versions exist of the Munin and Oesoca networks. The Barley and Mildew networks are used for agricultural purposes, the Water network models a water purification process and the OOW-trad, OOW-bas, OOW-solo, and Ship-ship networks are developed for maritime use. The rules are implemented in C++. All computations have been carried out on a Linux-operated PC with a 1700 MHz Intel Pentium 4 processor.

We discuss the results by means of four tables. Table 1 shows the results of preprocessing for (i) only the Simplicial rule, (ii) all described rules, and (iii) all described rules with initially *low* set to the MMNW+ lower bound. To illustrate the quality of the MMNW+ bound in comparison to the MMNW bound both values are presented in Table 2. Table 3 records the number of vertices preprocessed by each of the rules. Finally, in Table 4 the results of preprocessing for weighted treewidth are compared with those for (unweighted) treewidth.

The algorithm of Lauritzen and Spiegelhalter [13] works on a tree decomposition of the moralisation of the network. In the moralisation of a directed graph, for each pair of arcs with a common tail, an edge is added between the heads of the arc, and then all directions of arcs are dropped. Thus, in Table 1, the size of the graph after moralisation is shown (see [6] for the original sizes). Note that vertices with many incoming edges in the probabilistic network create a large clique in the moralisation. In Table 1, we show the size of the networks after each of the preprocessing strategies. Moreover the

Table 1: Preprocessing for weighted treewidth

value of *low* after preprocessing is reported as well as the initial value of *low* provided by the MMNW+ lower bound. To increase readability, the last column reports the computation times for the last strategy. Table 1 shows that application of the Simplicial rule only already results in substantial graph size reductions in all cases. On average over 50% of the vertices are removed by preprocessing (with a minimum of 18% and a maximum of 87%). Including all other preprocessing rules results in even more reduced graphs. For 6 out of 23 networks the graph is preprocessed to the empty graph and hence the weighted treewidth is given by the *low* for these instances. By application of the other rules, the Simplicial rule can be applied again and induces a further increase of *low* in four cases (note that *low* is not increased by rules other than the Simplicial rule and its special cases, the Islet rule and the Twig rule).

A third reduction can be shown by the use of an initial *low* value generated by a lower bound procedure. By the MMNW+ lower bound, *low* is increased for 16 networks and for 10 out of the 17 remaining networks the graph size is reduced further. The time needed to perform preprocessing is really small in comparison to the results achieved. Even the 34 seconds for the PigNet2 network is justifiable taking into account that the graph is reduced from 3034 to 1002 vertices. We only performed computations with MMNW+ as initial lower bound. In Table 2 the MMNW and MMNW+ lower bounds are compared. Although computation times are somewhat higher, the increase of the lower bound is substantially for many instances. Most impressive example is the result for the PigNet2 network ($3^{29} \approx 6.8 * 10^{13}$). This bound indicates that it is unlikely that the algorithm of [13] can be used for this network.

Table 3 allows us to have a closer look at the effectiveness of the various rules. We analysed the most general case in which the initial *low* was set to the MMNW+ lower bound. The order in which the rules are applied is important for a correct interpretation of this table. The rules are applied consecutively in the order they are mentioned in the table. In case a rule applies to the current graph, the rule is executed and the search is restarted with the first rule in the order (i.e., Islet). In this way, it is avoided that, for example, a simplicial vertex is processed by the Almost Simplicial rule.

As already observed in Table 1, the majority of the vertices is preprocessed by the Simplicial rule and its specialisations Islet and Twig. Notice that Islet is only applied if singletons are detected in the graph. Hence, Link contains at least 11 components, 10 of them preprocessed completely. The Series and Triangle rules are also applied regularly, whereas the more general Almost Simplicial rule is very successful for some instances. With one exception, the remaining rules are not applied at all. Only for the munin3 network 12

Table 4: Preprocessing for unweighted and weighted treewidth

Finally, in Table 4 we compare the results for preprocessing for weighted and unweighted treewidth. For (unweighted) treewidth, the value *low* can be increased to 4 in case the Islet, Twig, Series, Triangle, Buddy, and Cube rule cannot be applied anymore (cf. [3]). Compared with preprocessing for (unweighted) treewidth, less vertices are preprocessed by the same set of rules for weighted treewidth. Hence, at first sight the conclusion from this table may be that preprocessing for weighted treewidth is less effective than preprocessing for the unweighted notion. However, this conclusion is only half the truth. Of course less vertices could be processed by the more restrictive conditions for the rules. Also the unavailability of theoretical results to increase *low* further if certain rules cannot be applied anymore limits the effect of preprocessing. However, the advantage of preprocessing for weighted treewidth lies in the fact that the maximum weight of the bags X_i is considered. By reversing the preprocessing for (unweighted) treewidth, bags can be constructed with unnecessary high $w(X_i)$. The maximum value of $w(X_i)$ by reconstruction is pointed out by the columns "implied width" in Table 4. Although we do not know the weighted treewidth in most cases, for 6 networks this value is higher than the MMNW+ lower bound indicating that

the preprocessing is overreaching in this context. Most eye-catching result in this context is obtained for the VSD network. Reversing the preprocessing results in a value that is 50% higher than necessary.

7 Conclusions

Instances of NP-hard problems often can be reduced to equivalent but smaller instances using preprocessing techniques. For the problem of finding a tree decomposition for a weighted graph with minimal weighted width, we provided such a technique. Our method consists of the application of a set of reduction rules that allows for reduction of a weighted graph without increasing its weighted treewidth, and for which every reduction is easily reversible. We showed that several of the known reduction rules can be generated from the generic Contraction Reduction rule, and that new feasible reduction rules can be created. Furthermore, we presented techniques for getting lower bounds on the weighted treewidth. We leave the confluence of the rules as an interesting open problem (Conjecture 5.)

Experiments were conducted on the graphs of a set of probabilistic networks taken from real-life applications. These experiments revealed that a subset of the identified reduction rules were able to reduce the graphs significantly, or eliminate them even completely. Therefore, preprocessing by applying reduction rules is a very useful technique for the weighted treewidth problem.

Acknowledgements

We thank Linda van der Gaag for valuable suggestions and discussions for this research; furthermore we thank Kristian Kristensen, Anders L. Madsen, Kristian G. Olesen, Claus Skaaning Jensen, and Linda van der Gaag for providing instances of probabilistic networks.
