Abstract

About 20% of the German energy demand is supplied by natural gas. Additionally, for about twice the amount Germany serves as a transit country. Thereby, the German network represents a central hub in the European natural gas transport network. The transport infrastructure is operated by so-called transmissions system operators or TSOs. The number one priority of the TSOs is to ensure security of supply. However, the TSOs have no knowledge of the intentions and planned actions of the shippers (traders).

Open Grid Europe (OGE), one of Germany's largest TSO, operates a high-pressure transport network of about 12.000 km length. Since flexibility and security of supply is of utmost importance to the German Energy Transition ("Energiewende") especially with the introduction of peak-load gas power stations, being able to predict in- and out-flow of the network is of great importance.

In this paper we introduce a new hybrid forecast method applied to gas flows at the boundary nodes of a transport network. The new method employs optimized feature minimization and selection. We use a combination of an FAR, LSTM DNN and mathematical programming to achieve robust high quality forecasts on real world data for different types of network nodes.

Keywords: Gas Forecast, Time series, Hybrid Method, FAR, LSTM, Mathematical Optimisation

1. Introduction

About 20% of the German (and European) energy demand is met by natural gas. Additionally, for about twice the amount Germany serves as a transit country. Thereby, the German network represents a central hub in the European natural gas transport network. In light of the German Energy transition

("Energiewende") with an increasing share of renewable energy sources as well as the envisioned international transition towards substantially less fossil fuels and related greenhouse gas emissions, the importance of natural gas will increase even more. A critical task of gas power plants is to deliver electricity in peak load situations, where electricity from renewable energy sources is not sufficient to cope with the demands. From the gas network point of view this leads to huge gas demands on very short notice.

The gas network is operated by so-called transmissions system operators or TSOs. Their duty is to operate the long distance transport network and to ensure that all demands are met. Until 2005, gas transport and supply in Europe was provided by a handful of companies, owning and operating the natural gas transmission system to do so. To establish a European gas market, in 2005, the European Union legislated that gas trading and transport had to be done by mutual completely independent companies to ensure discrimination-free access to the transport network for all traders. Before this, TSOs were part of an integrated organization and could plan the network operation and expansion together with the traders. Since then, they are independent and need to plan under the uncertainty regarding the gas-flow situations resulting from trading. To ensure discriminatory free access to the network for all traders, there should be no information flow between shippers (traders) and the TSOs.

Although on the contractual level all gas transports have to be balanced, i.e., if gas gets out of the network the same amount has to be induced into the network, the network nodes where the gas is injected might be very far from the points where it is taken out of the network. Furthermore, the inflow might actually happen after the outflow. Practically, consumers like municipal power stations just draw gas out of the network as needed. They are required to also buy the same amount of gas to supply the network. But this may happen hours later at distant points of the network.

Despite of these challenges for the TSOs they need to meet all transport demands. It is the obligation of the TSO to monitor the situation, foresee possible shortages and react accordingly to ensure safety of supply. Since changes in gas networks happen rather slow it is therefore extremely important to have accurate forecasts on the demands and supply of the network to be able to react on time.

We collaborated with one of the biggest German TSOs, operating a gas network with pipe length of about 12,000 km in total (see Figure 1), to improve their hourly forecasts for demand and supply. We aim to:

- Predict as *precise* as possible the average hourly gas flows for the full the upcoming *gas day*, i.e., from 6am to 6am, just before the start of the gas day (at about 5:59am);
- The prediction needs to be appropriate for all different types of nodes

ranging from connections to other networks or countries to industrial users or municipal consumers, leading to very diverse data characteristics;

To reach these goals, we investigated real data from the transport network operated by Open Grid Europe. We propose a powerful and robust hybrid forecast model that benefits from the combination of state of the art forecasting approaches and optimisation, leading to to improved forecast accuracy. We interpreted the most important features, that our model automatically selects.

It should be noted that there is the following caveat. The TSO influences the resulting flow by its actions when controlling the network. Thus, the forecast includes a prediction of the actions of the dispatchers for whom the forecast is actually made for to guide their actions. Since based on measured in- and outflows of the network we cannot distinguish between customer demand and dispatcher action, for the purpose of this study we will ignore this.

In the following, the next subsections present nomenclature and an overview of related work. Section 2 describes the data we used in this study. Section 3 gives details on the proposed models. Section 4 describes the evaluation methodology and the evaluation of computational experiments. Finally, we draw some conclusions.

1.1. Nomenclature

Open Grid Europe GmbH	OGE
Municipal Power Stations	MUN

Baseline forecast(persistance)	BAS

1.2. Related work

Models on natural gas demand forecasting are mainly focused on long term issues. There are quite some publications regarding electricity demand forecasting, (see, e.g. [41], [23], [1], [25]) but electricity behaves very differently from gas. A survey on models to predict natural gas consumption published between 1949 and 2010 is presented by [36] who evidences that only a few works are focused on hourly gas flow prediction. A more recent survey ([45]) considers 187 papers published between 2002 and 2017. The authors point out that the majority of works provide daily predictions and recognize that neural networks are the most

used models. The authors also show that, on the considered period, most of the works were performed at an aggregated level (i.e. country or city) and only three papers proposed models to forecast the hourly gas consumption. In [43], two neural networks were tested to forecast natural gas consumption based on historical data and environmental variables. The authors found a better prediction accuracy when using the multi-layer perceptron compared to the radial basis function. In [42], a model similar to radial basis neural network was proposed to predict gas consumption in a distribution system. In this work input variables were selected using a genetic algorithm. Residential hourly gas consumption was predicted with neural networks by [10]. In this work, the heating degree-hour method which considers the gap between outdoor and indoor temperature was considered. The best hyper-parameters configuration consisted of 29 neurons, a feed-forward backpropagation algorithm and tangent, sigmoid and linear functions for the input, hidden and output layers respectively. Similarly, [39] proposed neural networks to forecast residential natural gas demand. The proposed network consisted of a multi-layer perceptrons with one hidden layer. The input features included calendar (i.e. month, day of the month, day of the week, hour) and weather (temperature) information. The authors found that average prediction error was higher during the winter months because gas flow was higher. More recently, [15] compared several machine learning models to predict residential natural gas hourly demand and found that recurrent neural network and linear regression were the most accurate models. The prediction results of monthly gas consumption of residential buildings using Extreme Learning Machine (ELM), artificial neural networks (ANNs) and genetic programming (GP) was presented by [16]. The ELM is characterized by higher training speed compared to backpropagation and it was found to perform better, in terms of RMSE, compared to the other two techniques. In [18] the authors set up a two stages methodology to predict daily gas consumption of utilities companies. In the first stage, two NNs are run in parallel to produce daily forecasts; in the second stage, a nonlinear transformation of some features of the input vector is performed. The combination of the two stages is based on several methods such as average forecast, recursive least squares, etc. The results show that the mix between the two forecasters have higher accuracy although the combination of the two models increase the complexity. Overall, these works shows that the consumer profile is very important when forecasting gas flow. In this regard, [32] identified seventeen groups profiles, based on their historical consumption and predicted daily gas demand. The overall prediction was obtained from the combination of the single predictions.

The backpropagation algorithm optimized with a genetic algorithm was implemented by [47] to increase the training speed and to achieve a global minimum. The authors predict next day gas loads based on temperature and weather conditions. Furthermore, the authors tested the algorithm on a three years real dataset recorded in Shanghai to predict one month and a half gas load. Similarly, [48] propose a recurrent neural network to predict daily gas flow. The Output-Input-Hidden Feedback-Elman neural network takes into account, not only the hidden nodes feedbacks but also considers the output nodes feedbacks.

The results improved compared to these obtained with standard Elman network. However, the authors recognize that further research is needed to forecast gas demand during holidays. In [3], an adaptive network-based fuzzy inference system (ANFIS) consisting of a neural network integrated with fuzzy logic was proposed to forecast short term natural gas demand. The main advantage of this model was its ability to handle uncertainty, noise and non-linearity in the data and, compared to standard neural network models, provided more accurate results. Wavelet transform have been deployed by [38] to decompose the hourly gas demand time series and Bi-LSTM and LSTM are optimized using genetic algorithm. The model was applied to winter data on which has shown good prediction accuracy. Several static and adaptive models have been tested by [30] for short-term gas consumption forecast (random-walk, temperature correlation model, linear regression model, ARX, adaptive (recursive) linear auto-regressive model (RARX), Neural Network (NN), Recurrent NN, Support Vector Regression). They found that the best performance was obtained by the RARX of order 3. Furthermore, they found that nonlinear models such as neural networks and support vector machines had a lower generalization capacity compared to linear models. Finally, they concluded that the adaptive models overall performed better than static models.

The traditional approaches are regression and econometrics models. In this regard, the performance of non linear mixed effects, ARIMAX and ARX models to predict gas consumption of 62 residential and small commercial customers was assessed by [8]. The authors forecast daily consumption of an entire month based on the previous 18 months. The time series included zero flows and missing data which were excluded for the training process. The prediction performance was similar in terms of daily mean absolute error which was closed to zero for all the tested models. Thus, the authors propose to combine multiple models although they recognize that this might be a difficult task because of increased computational complexity. Multiple linear regression has been proposed by [34] who predicted annual gas consumption based on socio-economic variables (GDP and inflation in the case of Turkey) that have been selected based on their statistical significance. Based on the forecast, the authors propose alternative energy policies.

A hybrid model formed by a grey model and an autoregressive integrated moving average model has been proposed by [46] to predict monthly gas shale production. The authors conclude that the results of the combined model are more accurate than the single linear and non linear models.

In [26], Multivariate Adaptive and Conic Multivariate Adaptive Regression Splines were proposed to predict residential daily gas demand. The two models provided better results in terms of prediction errors (MAE and RMSE) compared to these obtained with Linear regression and Neural Networks. In [35], the nonlinear characteristics of the natural gas consumption is modeled with several Grey models that are compared to predict the yearly natural gas consumption in China. Non linear programming and genetic algorithm have been proposed by [12] to predict natural gas consumption in the residential and commercial sectors on a yearly basis. Similarly, [17] proposed the breeder hybrid

algorithm which consists of three steps for natural gas flow demand forecast. In the first stage, the coefficients of a non linear regression model are estimated. Successively, the estimates are improved using genetic algorithm. Finally, the optimized coefficients are deployed as initial solutions for the simulated annealing. Nearest neighbor and local regression were proposed by [5] to predict gas flow in a small gas network with a 15 minutes resolution. The authors evidence the importance of environmental variables such as the temperature. Their method allowed to detect anomalies and the consumption patterns based on one year historical data. In the literature, there are also combinations of several methods to predict one day-head natural gas consumption. In [27], the time series was decomposed into low-frequency and high frequency components using Wavelet transform. In a second step, the genetic algorithm and Adaptive Neuro-Fuzzy Inference System were deployed to predict each of the decomposed time series. The output was finally fed into a feed-forward neural network to refine the prediction. The research was focused on different types of natural gas distribution points. The authors obtained better prediction results using the data of distribution points located near the city center. Neural networks have been also compared to the performance of autoregressive models. In [40], for instance, short term natural gas consumption in Turkey was predicted using SARIMAX model and Neural Networks (Multilayer and Radial Basis) and multivariate regression. They found that SARIMAX had better prediction performance. The temperature correlation model, proposed by [37], was compared with several configurations of ARX, stepwise regression, Support Vector Regression and Neural Network. The author found that SVR and NN performed better on the training set, while high order ARX model performed better on the test set. Support Vector Regression have been deployed with false neighbours filtered approach to predict short term natural gas consumption ([49]). The local predictor was based on the nearest neighbour approach so that the Euclidean distance between the training and test data and the neighbour filter was applied to determine the validity of the predicted values based on the exponential separation rate. The authors, obtained better performance prediction compared to ARIMA, Neural Networks and Support Vector Regression.

Overall, the analyzed literature shows that there are few works that are focused on the comparison between methods to predict hourly gas flow of different types of nodes in a gas network or combining the advantages of different forecasting methods to a hybrid model for hourly gas flows. Therefore, we propose a hybrid model based on optimisation and machine learning and compare its results to four different models to predict hourly gas flow. To address the heterogeneity of the time series for the different node types we compare results obtained for four different types of nodes.

2. Data

We consider high-resolution natural gas inflows and outflows in the high-pressure gas pipeline network operated by Open Grid Europe GmbH (OGE).

Table 1: Number of nodes and percentage of flow

Туре	num	flow(%)
Network	34	72.95
Municipal	726	16.68
Industry	234	4.26
Storage	14	6.11

The gas transmission network has more then 1000 boundary nodes which can be classified into four different groups:

- Municipal Power Stations (labeled MUN) are served for residential and small commercial constituents and contain only inflows as exits. These are often temperature depend, exhibit daily and seasonal patterns, and simultaneously are influenced by weekends/holidays.
- Power Stations and Industry (IND) represent electricity generation and factory production nodes. These are always exits and naturally exhibit weekly pattern due to working routines.
- Storage (STO) usually have a large number of zero flow hours with some substantial, often constant transfer in between.
- Transfer Points to other Networks (NET) are large nodes with natural gas imported and exported via Germany. These can be entries and/or exits.

While in principle, we know the above classification, it is proved not to be reliable regarding the behavior of the nodes, so we will not use this information as part of the forecast, but just to explain certain behavior.

The Table 1 shows number of nodes belonging to different groups and percentage of gas flow explained by each group.

As illustration, we carefully select three nodes for each type. The three largest network nodes we selected occupy 22 % percentage of the whole network flow. The municipal nodes are considered important by TSO with capacity product issued to market based on the future values. Industry nodes that we selected represent power plants and play the key role in energy generation. For the representative nodes from the Storage group we selected most frequently used nodes in the observed period.

The Figure 2 shows normalized (to the range of [0; 1]) flows of nodes considered in this study.

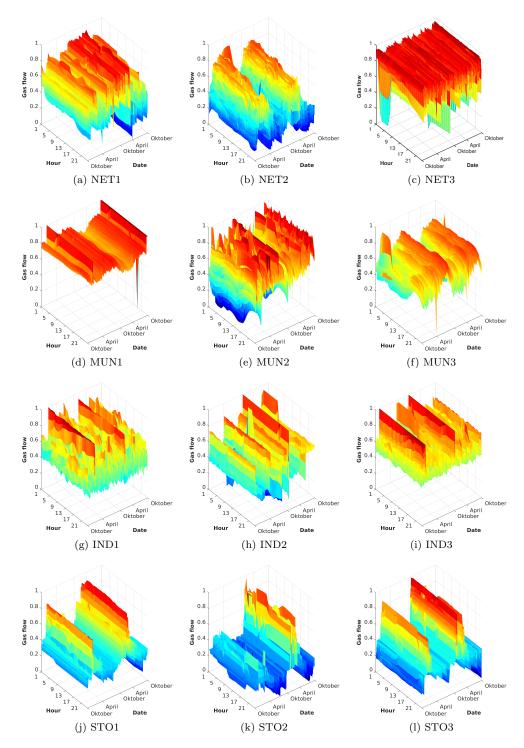

Figure 2: Normalized flow of selected nodes $\,$

For each node, the gas flows are measured hourly. Additionally, we were given the average daily temperatures measured at the nodes. Some statistical properties of selected nodes are given in Table 2. As can be seen from Figure 2 and in the Table 2 some nodes have continuous flow, while other are active only occasionally. Storage nodes have the highest percentage of zero flows, included between the 26% and 53% of the hours in the considered period. Network nodes show the highest variability and are always inflows. Industry nodes are always outflows and are clearly not temperature dependent. Municipal nodes are usually temperature dependent and have strong daily, weekly and seasonal patterns.

Table 2: Properties of nodes used in the study

Node	Туре	mean	std	min	max	zeros (%)
NET1	Network	13546	3177	4063	21092	0.00
NET2	Network	7752	3792	0	19113	0.01

3. Methods

One of the biggest challenges in selection of the best forecasting model is to choose a single model that represents all the complexity of the environment which affects behaviour of the dependent variable. Many research studies showed that combining forecasts improves accuracy relative to individual forecasts [20],[9]. In this Section we will first present three different individual forecasting methods; Mathematical Programming(MP), Functional AutoRegressive (FAR) and Long Short-Term Memory Network(LSTM) model. Then we will propose a hybrid model(HYB) based on MP method which is using output of two other forecasting models, FAR and LSTM, as additional inputs (features).

3.1. Mathematical Programming (MP) for time series forecasting

In this section, we use Linear Programs (LP) together with Mixed Integer Linear Programs (MILP) for prediction of the flows - supplies and demands of the gas network. We have a set of measurements $m_{d,h} \in M$ for $d \in D$ and

 $h \in H$. Let us define $M_d \subseteq M$ as a subset of the measurements before day d. We can approximate gas flow with weighted sum of features

$$p_{d,h} = \sum_{i \in F_h} w_{h,i} f_{h,i}(d) \tag{1}$$

where $p_{d,h}$ is the flow value which is approximated, $w_{h,i}$ define the weights, and $f_{h,i}$ are features.

The features $i \in F_h = \{1, \ldots, n_h\}$ are defined as arbitrary functions of historical flow values, $f_{h,i}(d): D \to M_d, i \leq p_h \leq n_h$ and exogenous variables $f_{h,i}(d), i \in \{p_h+1,\ldots,n_h\}$. The approximation error is defined as

$$e_{d,h} = p_{d,h} - m_{d,h}$$

and the optimal weights are calculated by minimizing the sum of absolute errors for each day d and hour h

$$\min \sum_{d \in D, h \in H} |e_{d,h}|$$

This problem is not a LP because of the nonlinear absolute value in the objective function but it can be transformed into a LP. We can rewrite the error $e_{d,h}$ as the difference of two non-negative variables:

$$e_{d,h} = e_{d,h}^+ - e_{d,h}^-$$

Then the transformed objective function is

$$\min \sum_{d \in D, h \in H} |e_{d,h}^+ + e_{d,h}^-|$$

It can be proven that in the optimal solution $e_{d,h}^+ * e_{d,h}^- = 0$ (ref) so we can write

$$|e_{d,h}^+ - e_{d,h}^-| = |e_{d,h}| + |e_{d,h}^-| = e_{d,h}^+ + e_{d,h}^-$$

and consequently the final LP problem becomes

$$\min \sum_{d \in D, h \in H} (e_{d,h}^+ + e_{d,h}^-)$$
s.t.
$$\sum_{i \in F} f_{h,i}(d) \cdot w_{h,i} - m_{d,h} = e_{d,h}^+ - e_{d,h}^- \forall d \in D, h \in H$$

$$e_{d,h}^+, e_{d,h}^- \ge 0$$

$$w_{h,i} \in \mathbb{R}$$

Furthermore, we can improve our model by requiring

$$\sum_{d \in D, h \in H} (e_{d,h}^+ - e_{d,h}^-) = 0$$

and setting bounds for the weights $l \leq w_{h,i} \leq u$ in order to prevent dominance of a single specific feature.

For each day in the test set (out of sample days that we want to forecast) the forecasted flow values are computed by first computing the weights via an LP with 16 weeks of historical data and then using the weighted sum of features (1) for each hour to forecast the flow values. The bounds for the weights are set to l=-2 and u=2. For the computation of the forecasted flow values, it might be that also forecasted flow values of prior hours are used as input values for calculating the features, if the corresponding hours do not lie in the past. The solution of the linear model leads to functions with which we can calculate the flow values for the different hours of the day which describe a iterative multi-step ahead multiple-input procedure with exogenous inputs.

Training: Feature Selection

In the training procedure of this method, a slightly different model is used which chooses for each hour the features which are important, to limit over-fitting in the LP. Therefore, we add additional binary variables $x_{h,i}$ to the problem, which determine whether feature i is chosen for hour h, i.e., whether the weight of feature i and hour h is not equal to zero. Then, we need to link these variables to the weight variables

$$x_{h,i} \cdot l \leq w_{h,i}^+ \leq x_{h,i} \cdot u$$

and limit the number of chosen features by B

$$\sum_{i \in F} x_{h,i} \le B$$

The solution of the resulting MILP leads for each hour h to one feature set F_h which seems to be important for this hour and is therefore chosen for the weighted sum of features and used in the LP.

Table 3: List of features

$\begin{array}{c} f_1(d,h) = \begin{cases} m(d,h-1), & \text{if } h > 0 \\ m(d-1,23) & \text{otherwise} \end{cases} & \text{Prior hour} \end{cases} \\ \hline f_2(d,h) = m(d-1,0) & \text{First hour yesterday} \\ f_3(d,h) = m(d-1,23) & \text{Last hour yesterday} \end{cases} \\ \hline f_{4:10}(d,h) = m(d-(1,2,,7),h) & \text{The same hour } 1,2,,7 \text{ days ago} \\ \hline f_{11:12}(d,h) = m(d-1,0(h))/m(d-2,0(h)) & \text{Ratio first(same) hour yesterday} \end{cases} \\ \hline f_{13:14}(d,h) = m(d-1,0(h)) - m(d-2,0(h)) & \text{Difference first(same) hour 2 days ago} \end{cases} \\ \hline f_{13:14}(d,h) = m(d-1,0(h)) - m(d-2,0(h)) & \text{Mean flow } 1,2,,7 \text{ days ago} \end{cases} \\ \hline f_{15:21}(d,h) = 1/24(\sum_{h \in H} m(d-(1,2,,7),h)) & \text{Mean flow } 1,2,,7 \text{ days ago} \end{cases} \\ \hline f_{22}(d,h) = f_{15}(d,h)/f_{16}(d,h) & \text{Ratio mean flow yesterday, 2 days ago} \end{cases} \\ \hline f_{23}(d,h) = f_{15}(d,h)/f_{21}(d,h) & \text{Ratio mean flow yesterday, 2 days ago} \end{cases} \\ \hline f_{24}(d,h) = f_{15}(d,h)/f_{21}(d,h) & \text{Ratio mean flow yesterday, 3 days ago} \end{cases} \\ \hline f_{25}(d,h) = f_{15}(d,h) - f_{16}(d,h) & \text{Difference mean flow yesterday, 2 days ago} \end{cases} \\ \hline f_{26}(d,h) = f_{15}(d,h) - f_{21}(d,h) & \text{Difference mean flow yesterday, 2 days ago} \end{cases} \\ \hline f_{26}(d,h) = f_{15}(d,h) - f_{21}(d,h) & \text{Difference mean flow yesterday, 3 days ago} \end{cases} \\ \hline f_{27}(d,h) = f_{15}(d,h) - f_{21}(d,h) & \text{Difference mean flow yesterday, 3 days ago} \end{cases} \\ \hline f_{28}(d,h) = \begin{cases} 0, & \text{if } h = 0 \\ m(d,0) & \text{otherwise} \end{cases} & \text{Mean flow today} \end{cases} \\ \hline f_{30}(d,h) = t_d - t_{d-1} & \text{Difference mean temperature today and yesterday} \end{cases} \\ \hline f_{31}(d,h) = \begin{cases} 1, & \text{if } day \in \{Saturday, Sunday\} \\ 0 & \text{otherwise} \end{cases} & \text{Weekend} \end{cases} \\ \hline f_{32}(d,h) = \begin{cases} 1, & \text{if } day \in \{Friday, Saturday\} \\ 0 & \text{otherwise} \end{cases} & \text{Offset} \end{cases}$	Feature	Description

The list of features used in this study is presented in Table 3. The whole set of features F we used consists of 29 different features based on historical flow values,1 temperature feature and 2 different features describing position of the predicted gas day in the week and the offset feature. Using sensitivity

analysis the number of chosen features was limited to 6. One year of historical measurements was used for training and selecting optimal set of features for every node and hour. The Figure 3 is showing the heatmap of selected features for MP model for each group of nodes summed up for 24 hours.

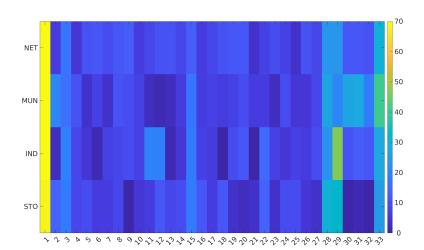

Figure 3: Heatmap of selected features for different node group

For all nodes the feature representing the flow of previous hour (f_1) is mostly used feature. For all hours except the first predicted gas hour this feature value is calculated based on the forecasted flow of previous hour when the final forecast is calculated. The same hour yesterday (f_4) is also widely selected among all groups. As it was expected Weekend (f_{31}) , Evening (f_{32}) as well as Mean temperature difference feature (f_{30}) are usually chosen only for the Municipal Power Stations since the behaviour of those nodes shows the strong daily, weekly and seasonal pattern. In the case of Industry nodes the features of Mean flow of the same and previous day (f_{29}, f_{15}) together with Ratio features f_{11}, f_{12} are most frequently chosen features. For Transfer Points and Storages features of mean flow of the same and previous day (f_{29}, f_{15}) are also dominated ones except for first gas hour where this pattern is not present. The Offset feature representing bias in the model has also very the high frequency of being selected for all observed nodes.

Figure 4 shows a scatter plots of flow versus three most frequently chosen features among different types of nodes for all hours of the day. It can be seen that flow depends linearly of f_4 while other features are showing a nonlinear dependency.

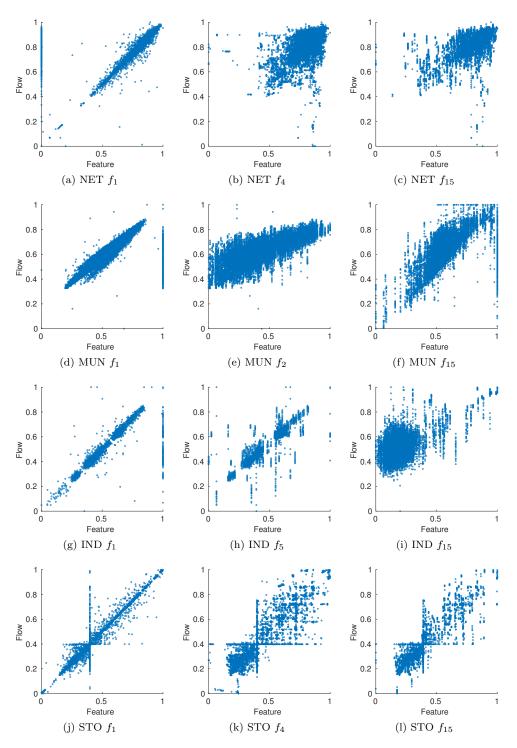

Figure 4: Scatter plot of some of frequently chosen features vs flow $\,$

3.2. Functional AutoRegressive (FAR) model

In this section, we consider the hourly gas flows as discrete observations in continuous daily flow curves and predict the continuous curves over time with Functional AutoRegressive (FAR) dynamics. [7] developed Functional AutoRegressive (FAR) model and Yule-Walker estimator for one series of functional time-dependent data ([6], Kim, [13], [2], [19]). [24] proposed a maximum likelihood estimation with Fourier expansions. Chen extended the maximum likelihood estimation with stochastic variations and employed an adaptive approach so that the predictive model can be directly applicable for both stationary and non-stationary situations. We detail the FAR setup and show how to obtain the maximum likelihood estimator of the functional parameters, with the help of Fourier expansion and sieve.

Our interest is to model the dynamic dependence of gas flow curves over time. Let $\left\{X_t(\tau)\right\}_{t=1}^n$ denote a sequence of random curves over a time domain $\tau \in [0,1]$. The curve $X_t(\tau)$ is a continuous function taken values in the Hilbert space \mathcal{H} endowed with its Borel σ -algebra $B_{\mathcal{H}}$ at time point t. Suppose that there exists a Hilbert-Schmidt operator ρ_t that can be written as $\rho_t = \sum_j \lambda_{j,t} < \cdot, e_j > f_j$, where $\{e_j\}$ and $\{f_j\}$ are orthonormal bases of $\mathcal{H}, <\cdot, \cdot>$ is the inner product derived to Hilbert-Schmidt norm $||\cdot||$, and $\{\lambda_j, t\}$ is a real sequence such that $\sum_j \lambda_{j,t}^2 < \infty$, see [7] for the theory of Hilbertian autoregressive model. The functional autoregressive model of order 1, i.e. the FAR(1) model, is defined as:

$$X_{t}(\tau) - \mu(\tau) = \int_{0}^{1} K(\tau - s)[X_{t-1}(s) - \mu(s)]ds + \varepsilon_{t}(\tau), \quad \tau \in [0, 1], \quad (2)$$

where $\mu(\tau)$ is the time-dependent mean function of $X_t(\tau)$. The AR operator is represented as a convolution kernel operator, which is one implementable form of the Hilbert-Schmidt operator. This choice of convolution kernel operator is very common in the study of functional linear processes and autoregressive processes, see [31], [24] and [22]. The kernel $K \in L^2([0,1])$ is an even function with $||K||_2 < 1$ and $||\cdot||_2$ denotes the standard L^2 norm. The innovation $\varepsilon_t(\tau)$ is a strong \mathcal{H} -white noise with zero mean and finite second moment $E||\varepsilon(\tau)||^2 < \infty$ Assume the Fourier coefficients of the innovation function $\varepsilon_t(\tau)$, denoted as $a_0(\varepsilon_t), a_k(\varepsilon_t)$ and $b_k(\varepsilon_t)$, are independent and identically Gaussian distributed with mean zero and variance σ_k^2 , we define a transition density as follows:

$$g(X_{t}, X_{t-1}, \rho) = \frac{2\pi^{-(2m_{n}+1)/2}}{\sigma_{0} \prod_{k=1}^{m_{n}} \sigma_{k}^{2}} \cdot \exp\left\{-\frac{1}{2\sigma_{0}^{2}} (a_{t,0} - p_{0} - c_{0} a_{t-1,0})^{2} - \sum_{k=1}^{m_{n}} \frac{1}{2\sigma_{k}^{2}} \left[(b_{t,k} - q_{k} - \frac{1}{\sqrt{2}} c_{k} b_{t-1,k})^{2} + (a_{t,k} - p_{k} - \frac{1}{\sqrt{2}} c_{k} a_{t-1,k})^{2} \right] \right\},$$

and thus the conditional log-likelihood $L(X_1,...,X_n;\rho)$ is

$$L(X_1, ..., X_n; \rho) = \log \left\{ \prod_{t=2}^n g(X_t, X_{t-1}, \rho) \right\}$$

$$= -\frac{(2m_n + 1)(n - 1)}{2} \log 2\pi - (n - 1) \log \sigma_0 - (n - 1) \sum_{k=1}^{m_n} \log \sigma_k^2$$

$$-\frac{1}{2\sigma_0^2} \sum_{t=2}^n (a_{t,0} - p_0 - c_0 a_{t-1,0})^2$$

$$-\sum_{t=2}^n \sum_{k=1}^{m_n} \frac{1}{2\sigma_k^2} \left\{ (b_{t,k} - q_k - \frac{1}{\sqrt{2}} c_k b_{t-1,k})^2 + (a_{t,k} - p_k - \frac{1}{\sqrt{2}} c_k a_{t-1,k})^2 \right\}.$$

We implement the FAR modelling to forecast the daily gas flow curves. The gas flow forecast h-step ahead, denoted as $\hat{X}_{t+h}(\tau)$ is directly based on the h-step ahead forecast of the mean function and the kernel operator:

$$\hat{X}_{t+h}(\tau) = \hat{\mu}(\tau) + \int_0^1 \hat{K}(\tau - s)[X_t(s) - \hat{\mu}(s)]ds$$
 (3)

For each forecast point, we estimate the Fourier coefficients to obtain the estimated mean function $\hat{\mu}(\cdot)$ and kernel operator $\hat{K}(\cdot)$ and the fitted model is then used to compute h = 1- and 2-step ahead forecasts of the gas flow curves.

3.3. Long Short-Term Memory Network

In this section, we use Long Short-Term Memory Network (LSTM) to predict gas flow based on the previous 24-hours. LSTM are a special types of Recurrent Neural Networks (RNN) that have been introduced in the eighties (i.e. [33], [11]) to model time interrelations by allowing connection between hidden units with a time delay ([28]). At each iteration, the hidden state vector receives the input vector and its previous hidden state. The hidden state vector can, therefore be seen as a representation of time sequences ([29]).

Long Short-Term Memory (LSTM) networks, proposed by [14], include a memory gate that controls what passes through the network and what is blocked so that some of the information that is feedback to the network is remembered and some other is forgotten. An additional gate keeps memory and filters out what has to be forgotten. At each time step, the network memorizes the information and filters out what is not relevant for the prediction. Finally, another set of gates ignores what is irrelevant. The formulation of the LSTM, as presented in [21], consists of three layers that are called gates: the input (4), forget (5) and output gates (8), respectively:

$$i = sig(W_i[h_{t-1}, x_t] + b_i)$$

$$\tag{4}$$

$$f = sig(W_f[h_{t-1}, x_t] + b_f)$$

$$\tag{5}$$

Where h_{t-1} is the hidden state computed at time t-1 which is calculated based on previous hidden state, h_t . Each of the gate has a sigmoid function so that the values range between 0 and 1.

The decision on which information will be stored into a cell is based on the input layer (4) and on a hyperbolic tangent (or sigmoid) function assigned to the layer that returns the set of candidate values, \hat{C} (6):

$$\hat{C}_t = tanh(W_C[h_{t-1}, x_t] + b_C) \tag{6}$$

To update the cell state C_{t-1} into C_t , the old state is multiplied by the forget gate and added to the new candidate values (7):

$$C_t = f_t \circ C_{t-1} + i \circ \hat{C}_t \tag{7}$$

Finally, the output is obtained by passing the cell state C_t to a rectified linear function (or hyperbolic tangent) function to decide which part of the information is passed to the output 8. Moreover, the cell state is multiplied by the output of the relu (or tanh) gate (9).

$$o_t = sig(W_o[h_{t-1}, x_t] + b)$$
 (8)

$$h_t = tahn(C_t) \circ o_t \tag{9}$$

Thanks to this architecture, LSTM has the ability to look back several time steps and, thus, to improve the predictions. Also recurrent neural networks can look time steps back but the problem they incur is called vanishing or exploding gradient for which the results either become very large or small.

The LSTM deployed to forecast gas flow consisted of one single layer and an early stop function with patience set to four. This means that the training of the network stops as soon as the value of loss function remains the same after four iterations. In this work, different types of parameters are manually selected to forecast gas flow depending on the type of node and based on trial and error.

The configuration of the parameters of the network for each node is reported in Table 4. The most influential parameter is the batch size that is the number of training examples that are utilized in each iteration. The higher is the value of this parameter the faster is the training of the network. Only two types of activation functions are selected for the hidden state, depending on the node: hyperbolic tangent function (tanh) or sigmoid. The transfer function of the output gate selected for all nodes, except for one network node, is the Rectified Linear Unit (Relu). Overall for storage nodes that are characterized by high variability between negative and positive values and by a high number of hours with zero flows, the batch size was set between 48 and 80 and the number of neurons between 70 and 80.

Table 4: Parameters of the LSTM

Node	Neurons	Dropout	Activation	Activation Output	Batch size

STO2	80	0.7	Tanh	Relu	80
STO3	80	0.7	Tanh	Relu	80

3.4. Hybrid model

The main advantage of the mathematical programming method(MP) proposed in this paper is flexibility in the sense that adding new features when they are available in order to improve the forecast is very simple.

In this section we propose a hybrid model, combining mathematical programming (MP) with two other proposed methods by adding the outputs from LSTM and FAR model as an exogenous inputs to MP model. The optimal sets of features chosen for every node and hour were kept from previous MP training and extended with the forecasts from the LSTM and FAR model as an additional features. The final forecast is calculated as weighted sum of all features from extended features set:

$$p_{d,h} = p_{d,h} = \sum_{i \in F} f_{h,i}(d) \cdot w_{h,i} + LSTM(d,h) \cdot w_{h,LSTM} + FAR(d,h) \cdot w_{h,FAR}$$

New optimal weights are calculated by running an LP:

$$\min \sum_{d \in D, h \in H} (e_{d,h}^{+} + e_{d,h}^{-})$$

$$\text{s.t.} p_{d,h} - m_{d,h} = e_{d,h}^{+} - e_{d,h}^{-} \forall d \in D, h \in H$$

$$p_{d,h} = \sum_{i \in F} f_{h,i}(d) \cdot w_{h,i} + LSTM_{h}(d) \cdot w_{h,LSTM} + FAR_{h}(d) \cdot w_{h,FAR}$$

$$e_{d,h}^{+}, e_{d,h}^{-} \ge 0$$

$$w_{h,i}, w_{h,LSTM}, w_{h,FAR} \in \mathbb{R}$$

where $LSTM_h(d)$ and $FAR_h(d)$ represent forecasted values obtained from LSTM and FAR model respectively.

4. Testing and Results

4.1. Influence of temperature

The temperature is one of the most important factors that influence gas consumption. When the natural gas is consumed for heating and cooking such as in residential areas, the temperature usually has an inverse relationship with gas consumption which is also dependent on other environmental data such as the time of day, the day of week, the season, etc. Overall, the forecast error is higher during the winter months because the demand for gas is higher. Furthermore, temperature and time of day are the factors that mostly impact the forecast error ([39]).

The majority of models presented in the literature are focused on residential and small commercial consumer at individual or aggregate level.

Several authors have considered the temperature (i.e. [26], [27], [12]) or meteorological data ([40]) in their models to forecast gas flow and reduce the prediction error.

In [44], the authors pointed out that the nonlinear characteristics of temperature has been assessed long time ago and gas consumption is proportional to the Heating Degree Day (HDD) ([4]). This proportionality is evidenced when plotting the average daily temperature with versus the gas consumption.

The scatter plots of daily changes of temperature versus daily changes of gas flow of the nodes considered in this work are showed in Figure 5. Storage nodes have high percentage of zero flows, those are the nodes that better approximate the non linear relationship expressed by the HDD. As expected, the Municipal nodes present a positive correlation between the flow and the temperature. Among the network nodes, one of them presents a negative relationship with the temperature. The remaining nodes appear to be independent from the temperature.

4.2. Results

4.2.1. Objectives, setup and evaluation metrics

In this paper we observed a data set of hourly gas flow time series from twelve nodes with 17.520 observations (two years).

Let us denote the set of hours by H, the set of gas days by D, the set of measured values by $m_{dh} \in M$, the temperatures by $t_d \in T$.

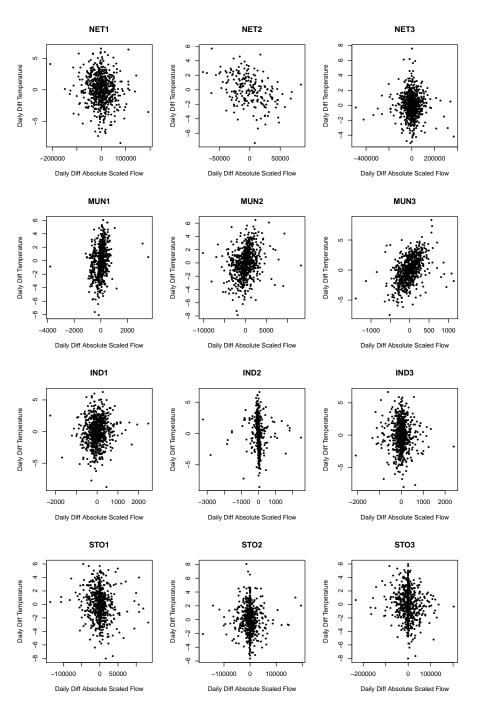

Our goal is to predict values $p_{d,0}$ to $p_{d,23}$ for a given $d \in D$. Of course only data for days d-1 and earlier can be used. All proposed methods are tested on the last 60 days of the data set.

Our basis comparison are the mean absolute deviation (MAD) between the hourly forecast and the measured flow during one day (24h) ahead forecast, defined as

$$MAD_d := 1/h \sum_h |p_h - m_h|$$
 (10)

and mean absolute percentage error (MAPE) defined as

Figure 5: Scatter plot of gas consumption vs temperature

$$MAPE_d := 1/h \sum_h |p_h - m_h/m_h|$$
 (11)

All results are also compared to a baseline (BAS) forecast defined as

$$\hat{p}_{h,d} := m_{h,d-1} \tag{12}$$

4.2.2. Results

Mean MAD and MAPE (over 60 days in the test set) achieved by proposed models are presented in the Table 5.

Table 5: Comparison of mean daily performance

			MAPE					MAD		
	MP	FAR	LSTM	HYB	BAS	MP	FAR	LSTM	HYB	BAS

STO3	0.895	0.970	0.475	0.502	0.997	895	1155	909	816	1442

It can be seen that between individual forecasting methods LSTM model is the most robust one and obtained the best results for nodes from all 4 behavior groups. The MP model achieved the best results for two Municipal Power Stations, and the performance is especially good for MUN2 node where all models had a particularly high MAPE. FAR model outperformed others for the Industry node IND2. Even though FAR errors are slightly higher than other two proposed models(MP and LSTM) it can be seen that for most of the nodes the performance is very similar. For Storage nodes with intermittent behaviour none of the proposed individual methods has demonstrated adequate accuracy. The Hybrid model showed an improvement for all 4 groups nodes. Nodes NET1 and NET3 The improvement is especially significant for Storage nodes, where the average MAPE is lower for more than 2(%) for nodes STO1 and STO2. For node STO3 LSTM model has the lowest MAPE but the lowest MAD is achieved by HYB model.

Figure 6 shows calculated 24 hours ahead forecast and the measured flow of all proposed models for one week period.

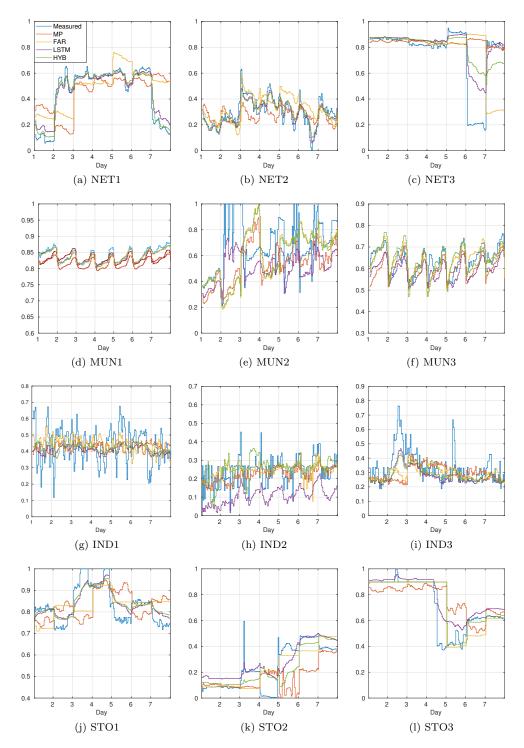

Figure 6: 24 hours ahead forecast for one week test set

5. Conclusions

In this paper we proposed a robust and powerful hybrid forecast model combining Mathematical Programming with Functional AutoRegressive and Long Short Term Neural Network model for forecasting gas flows at the boundary nodes of gas transport network. Our experiments are based on real world data from one of Germany's largest transmission system operators, Open Grid Europe. We showed taht the proposed method is appropriate for choosing optimal set of features and forecasting various behaviours from different nodes groups in the complex gas transmission network. From obtained results it is clear that even though in some specific cases single forecast models outperform the Hybrid model, the proposed method can achieve stable accuracy close to the best individual model and in some cases brings the significant improvement to the forecast quality.
