Abstract

Public transportation networks are typically operated with a periodic timetable. The Periodic Event Scheduling Problem (PESP) is the standard mathematical modelling tool for periodic timetabling. Since PESP can be solved in linear time on trees, it is a natural question to ask whether there are polynomial-time algorithms for input networks of bounded treewidth. We show that deciding the feasibility of a PESP instance is NP-hard even when the treewidth is 2, the branchwidth is 2, or the carvingwidth is 3. Analogous results hold for the optimization of reduced PESP instances, where the feasibility problem is trivial. To complete the picture, we present two pseudo-polynomial-time dynamic programming algorithms solving PESP on input networks with bounded tree- or branchwidth. We further analyze the parameterized complexity of PESP with bounded cyclomatic number, diameter, or vertex cover number. For event-activity networks with a special – but standard – structure, we give explicit and sharp bounds on the branchwidth in terms of the maximum degree and the carvingwidth of an underlying line network. Finally, we investigate several parameters on the smallest instance of the benchmarking library PESPlib.

1 Introduction

Creating and optimizing timetables is substantial for planning and operating public transportation networks. As well as in local traffic as in long-distance train networks, timetables are often periodic, i.e., the schedule of trips repeats after a certain period time T, e.g., 60 minutes.

Mathematically, periodic timetabling is captured by the *Periodic Event Scheduling Problem* (PESP, Serafini and Ukovich, 1989). The idea behind PESP is to model arrival and departure events of trips in a public transportation network as vertices (*events*) of a directed graph. Dependencies between events, such as driving of a vehicle or changing at a station, are modeled as arcs (*activities*) connecting pairs of events. These activities come with restrictions on their duration, e.g., driving from one station to the next might take at least 7 minutes. Then, a solution to PESP is an assignment of times in [0, T) to each event (a *periodic timetable*) such that the activity duration restrictions are respected. We refer to Section 2 for rigorous formulations.

Deciding whether a periodic timetable exists is an NP-complete problem, even if $T \geq 3$ is not considered as part of the input. This result can be proved by a polynomial-time reduction of T-VERTEX COLORING, where a T-coloring of a graph corresponds to event times

^{*}Funded by Deutsche Forschungsgemeinschaft (DFG, German Research Foundation) under Germany's Excellence Strategy – The Berlin Mathematics Research Center MATH+ (EXC-2046/1, project ID: 390685689).

in $\{0,1,\ldots,T-1\}$ (Odijk, 1994). This suggests a close relationship between PESP and coloring problems. In fact, both PESP and VERTEX COLORING are solvable in linear time on trees, regardless of T. Furthermore, for any T, deciding if a graph admits a T-coloring is fixed-parameter tractable when parameterized by treewidth. More precisely, there is a function f such that for a given graph G on n vertices with a nice tree decomposition of treewidth $\leq k$ and a natural number T, there is an $O(f(k) \cdot n)$ algorithm deciding the T-VERTEX COLORING problem on G (Arnborg and Proskurowski, 1989).

We show in Section 3 that no such result holds for PESP: Even if the event-activity network has treewidth 2 or branchwidth 2, i.e., every connected component is series-parallel, it is an NP-complete problem to decide whether a feasible periodic timetable exists. When considering *reduced* PESP instances, where the activities carry only lower bounds, but no (non-trivial) upper bounds, we prove that it is NP-complete to decide if there exists a periodic timetable whose weighted periodic slack is below a given threshold. Both proofs work by a reduction of the SUBSET SUM problem. As a byproduct, we also obtain an NP-hardness result on networks of carvingwidth 3. As a consequence, if $P \neq NP$, then there are only pseudo-polynomial time algorithms available for both the feasibility and the reduced optimality problem. We give two such algorithms based on dynamic programming in Section 4, one in terms of a branch decomposition, and the other one in terms of a nice tree decomposition.

In Section 5, we prove that the feasibility version of PESP is fixed-parameter tractable when parameterized by the cyclomatic number, i.e., the dimension of the cycle space of the event-activity network. For computing periodic timetables with minimum weighted periodic slack, we give a polynomial-time algorithm when the cyclomatic number is bounded. We further discuss the diameter as a parameter. Some generalizations of the VERTEX COLORING problem like, e.g., L(2,1)-LABELING, are also NP-complete on graphs of treewidth ≥ 2 , but are fixed-parameter tractable when parameterized by the vertex cover number, i.e., the cardinality of a minimum vertex cover (Fiala et al., 2011). We prove that deciding the feasibility of a PESP instance is W[1]-hard when parameterized by the vertex cover number.

As PESP instances arising from public transportation networks typically have a special structure, we show in Section 6 that on this type of event-activity networks, the branchwidth can be related to invariants of an underlying line network: Roughly speaking, the number of lines at a station of a public transport network is a (sharp) lower bound on the branchwidth of the event-activity network. The carvingwidth of the often planar line network provides an upper bound, which is also sharp. Finally, we consider the smallest instance R1L1 of the PESP benchmarking library PESPlib, and use the relation to line networks in order to compute bounds on the width parameters discussed in this paper.

The presentation finishes with a few concluding remarks in Section 7.

2 The Periodic Event Scheduling Problem

The *Periodic Event Scheduling Problem* (PESP) was introduced in (Serafini and Ukovich, 1989). PESP instances comprise the following ingredients:

- a directed graph G (often called *event-activity network*) with vertex set V(G) (*events*) and arc set A(G) (*activities*),
- a period time $T \in \mathbb{N}$,
- lower bounds $\ell \in \mathbb{Z}_{\geq 0}^{A(G)}$, $\ell < T$,
- upper bounds $u \in \mathbb{Z}_{\geq 0}^{A(G)}$, $u \geq \ell$,

• weights $w \in \mathbb{Q}_{>0}^{A(G)}$.

In the application of periodic timetabling in public transport, the events are typically arrivals or departures of a line at a station, and activities model driving between stations, dwelling at a station, passenger transfers, or safety constraint such as minimum distances between vehicles (Liebchen and Möhring, 2007). The weights often reflect the number of passengers using an activity.

Definition 2.1. Given (G, T, ℓ, u) as above, a *periodic timetable* is a vector $\pi \in [0, T)^{V(G)}$ such that there exists a *periodic tension* $x \in \mathbb{R}^{A(G)}_{>0}$ satisfying

$$\forall ij \in A(G): \quad \ell_{ij} \leq x_{ij} \leq u_{ij} \quad \text{and} \quad \pi_j - \pi_i \equiv x_{ij} \mod T.$$
 (1)

Intuitively, π gives the cyclic order of the events, and x corresponds to the duration of the activities. If there exists a periodic timetable π , then a periodic tension can be computed by

$$x_{ij} := [\pi_i - \pi_i - \ell_{ij}]_T + \ell_{ij}, \quad ij \in A(G), \tag{2}$$

where $[\cdot]_T$ denotes the modulo-T-operator taking values in [0,T). Conversely, from a vector $x \in \mathbb{R}^{A(G)}_{\geq 0}$ with $\ell \leq x \leq u$, one can construct a periodic timetable with tension x by a graph traversal, see also Lemma 2.7.

In terms of the incidence matrix $B \in \{-1,0,1\}^{V(G) \times A(G)}$, condition (1) can be rewritten as

$$\ell \le x \le u$$
 and $B^t \pi \equiv x \mod T$.

Since B and hence are B^t are totally unimodular (Schrijver, 1986, Example 19.2) and the bounds ℓ , u are integer, it follows that if a periodic timetable exists, then there is also an integer timetable with an integer periodic tension. However, in general, it is not at all clear that a periodic timetable exists:

Definition 2.2 (*T*-PESP-FEASIBILITY). Given a tuple (G, T, ℓ, u) as above, decide if there exists a periodic timetable π .

Theorem 2.3 (Odijk, 1994). *T*-PESP-FEASIBILITY *is* NP-complete for fixed $T \ge 3$.

Proof. It is clear that T-PESP-FEASIBILITY is in NP, as a feasible timetable π with periodic tension x serves as certificate. We recall the proof in order to emphasize the natural relationship between PESP and VERTEX COLORING. Fix $T \geq 3$. Given an undirected graph H, construct a T-PESP-FEASIBILITY instance (G, T, ℓ, u) as follows: G is obtained from H by arbitrarily directing the edges, and set $\ell := 1$, u := T - 1. Then, H admits a T-coloring if and only if (G, T, ℓ, u) has a periodic timetable π . Namely, if $f : V(H) \rightarrow \{0, \ldots, T - 1\}$ is a T-coloring, then setting $\pi_i := f(i)$ for all $i \in V(G)$ is a periodic timetable, as for every arc $ij \in A(G)$ then holds $x_{ij} = [\pi_j - \pi_i]_T = [f(j) - f(i)]_T \in [1, T - 1]$. Vice versa, if the PESP instance is feasible, then there is an integer timetable, giving rise to a T-coloring.

So far, we have neglected the weight vector $w \in \mathbb{Q}_{\geq 0}^{A(G)}$. The weights come into play in the optimization variant of PESP, which we state as its corresponding decision version. If x is a periodic tension, we call $y := x - \ell \geq 0$ the *periodic slack*.

Definition 2.4 (*T*-PESP-OPTIMALITY). Given (G, T, ℓ, u, w) as above and a number M, find a periodic timetable π with periodic slack y such that $w^t y \leq M$.

Minimizing the weighted periodic slack, or equivalently, the weighted periodic tension, can be interpreted as minimizing the total travel time of all passengers in a public transportation network. Clearly, T-PESP-OPTIMALITY is an NP-hard optimization problem. However, in many non-railway public transport networks, minimum distances are neglected for planning, and the driving and dwelling times of vehicles have a rather small span, so that they can be assumed as fixed. Contracting the corresponding activities yields a graph where only transfer activities remain, and these have typically no restrictions on their durations in the sense that lower and upper bounds differ by at least T-1. This motivates the following specialization of PESP, sometimes called *reduced PESP*:

Definition 2.5 (*T*-RPESP-OPTIMALITY). Given (G, T, ℓ, u, w) as above with $u \ge \ell + T - 1$ and a number M, find a periodic timetable π with periodic slack y such that $w^t y \le M$.

Note that the feasibility problem is trivial to solve: *Any* integral vector $\pi \in [0, T)^{V(G)}$ is a periodic timetable, because for any activity $ij \in A(G)$,

$$\ell_{ij} \le x_{ij} = [\pi_j - \pi_i - \ell_{ij}]_T + \ell_{ij} \le T - 1 + \ell_{ij} \le u_{ij}.$$

Theorem 2.6 (Nachtigall, 1993). *T*-RPESP-OPTIMALITY is NP-hard for any fixed $T \ge 3$.

Proof. We adapt the proof of Nachtigall to our notions and notations. Fix some period time $T \geq 3$. We reduce T-PESP-FEASIBILITY to T-RPESP-OPTIMALITY. Let (G,T,ℓ,u) be a T-PESP-FEASIBILITY instance. Without loss of generality, assume that $u-\ell < T$, because if the instance is feasible, then there is a periodic tension x satisfying $x < \ell + T$ by (2). Add to each arc $a \in A(G)$ from i to j a reverse copy \overline{a} with $\ell_{\overline{a}} := [-u_a]_T$. Set all weights w to 1. For this T-RPESP-OPTIMALITY instance, let π be a periodic timetable with tension x as defined in (2). Then for any original arc a holds $\ell_a \leq x_a < \ell_a + T$ and $x_a \equiv -x_{\overline{a}} \mod T$. For the slacks y_a and $y_{\overline{a}}$, we obtain

$$y_a + y_{\overline{a}} = [x_a - \ell_a]_T + [u_a - x_a]_T.$$

Since $0 \le x_a - \ell_a \le u_a - \ell_a < T$ and $-T < \ell_a - x_a \le u_a - x_a \le u_a - \ell_a < T$,

$$y_a + y_{\overline{a}} = \begin{cases} u_a - \ell_a & \text{if } u_a - x_a \ge 0, \\ u_a - \ell_a + T & \text{if } u_a - x_a < 0. \end{cases}$$

In particular, for the weighted slack of the T-RPESP-Optimality instance holds

$$\sum_{a\in A(G)}(y_a+y_{\overline{a}})\geq \sum_{a\in A(G)}(u_a-\ell_a),$$

and equality holds if and only if $x_a \leq u_a$ for all $a \in A(G)$. This means that the *T*-PESP-FEASIBILITY instance is feasible if and only if the described *T*-RPESP-OPTIMALITY instance has weighted periodic slack at most $M := \sum_{a \in A(G)} (u_a - \ell_a)$.

We turn now to simple algorithms for T-PESP-OPTIMALITY. Consider at first instances where undirecting the event-activity network results in a tree (shortly, G is a tree):

Lemma 2.7. *If* G *is a tree on n vertices, then* T-PESP-OPTIMALITY *on* (G, T, ℓ, u, w) *can be solved in* O(n) *time. Morever,* ℓ *is an optimal periodic tension, and the minimum weighted periodic slack is* 0.

Proof. If undirecting G results in a tree on n vertices, then the transpose B^t of the incidence matrix B of G is a $(n-1) \times n$ matrix of full rank n-1. In particular, $B^t \pi = \ell$ has a solution over \mathbb{Z} , and reducing modulo T gives a feasible periodic timetable π^* with periodic tension ℓ and hence weighted periodic slack 0.

Avoiding linear algebra, π^* can as well be obtained by traversing the tree, starting with $\pi_v^* = 0$ at an initial vertex v and setting $\pi_j^* := [\pi_i^* + \ell_{ij}]_T$ when traversing $ij \in A(G)$, and $\pi_j^* := [\pi_i^* - \ell_{ij}]_T$ if $ji \in A(G)$ is traversed. A depth-first traversal takes O(|V(G)| + |A(G)|) = O(n) time.

On general networks, there are several ways to give naive exponential-time algorithms for *T*-PESP-OPTIMALITY:

Lemma 2.8. On instances (G, T, ℓ, u, w) with n events and m activities, T-PESP-OPTIMALITY can be solved in

- 1. $O^*(T^{n-1})$, or
- 2. $O^*(2^{n-1}n^{n-2})$, or
- 3. $O^*(3^m)$ time,

where $O^*(\cdot)$ means $O(\cdot)$ ignoring polynomial factors.

Proof.

- 1. Enumerate all T^n integral vectors in $[0,T)^{V(G)}$, compute x by (2), and check the bounds. This is an $O(mT^n)$ algorithm. If π is a periodic timetable, then for any $d \in \mathbb{R}$, π' defined by $\pi'_i := [\pi_i + d]_T$ for all $i \in V(G)$ is a periodic timetable with the same periodic tension. In particular, only T^{n-1} vectors have to be enumerated.
- 2. By Nachtigall (1998), if G is weakly connected and the instance is feasible, there is an optimal periodic tension x^* and a spanning tree F of G such that $x_a^* \in \{\ell_a, u_a\}$ for all $a \in A(F)$. Enumerate all $O(n^{n-2})$ spanning trees F of G. For each such F, enumerate all 2^{n-1} vectors $x \in \prod_{a \in A(F)} \{\ell_a, u_a\}$. Interpreting x as a periodic tension defines a periodic timetable $\pi \in [0, T)^{V(G)}$ which can be computed by an O(n+m) depth-first traversal as in the proof of Lemma 2.7 (replacing ℓ by x). Use (2) to compute the periodic tension x_a of all O(m) remaining co-tree arcs $a \notin A(F)$ and check if the bounds are satisfied. If G is not connected, T-PESP-OPTIMALITY can be solved on each component individually.
- 3. Let B denote the incidence matrix of G. Then the modulo constraint $B^t\pi \equiv x \mod T$ is satisfied if and only if there is a vector $p \in \mathbb{Z}^{A(G)}$ such that $B^t\pi = x Tp$. Since any entry of $B^t\pi$ lies in the interval (-T,T), and any tension computed by (2) satisfies $x \in [0,2T)$, it suffices to consider $p \in \{0,1,2\}^{A(G)}$, cf. Liebchen (2006, Lemma 9.2). The algorithm is now to solve the problem

Minimize
$$w^t y$$

s.t. $B^t \pi = x - Tp$, $\ell < x < u$

for each fixed $p \in \{0,1,2\}^{A(G)}$. This is a series of 3^m linear programs.

Somewhat unsurprisingly, Lemma 2.8 implies that all three presented PESP variants are solvable in polynomial time when the number of events or the number of activities is fixed. In the remainder of the paper, we investigate several graph parameters and their effects on the parameterized complexity of PESP, starting with treewidth.

3 PESP on Networks of Treewidth Two

3.1 Subset Sum

Definition 3.1 (Garey and Johnson, 1979, SP13). The SUBSET SUM problem is the following: Given $r \in \mathbb{N}$, $c \in \mathbb{Z}_{\geq 0}^r$ and $C \in \mathbb{Z}_{\geq 0}$ with $C \leq \sum_{i=1}^r c_i$, is there a $z \in \{0,1\}^r$ such that $c^t z = C$?

The SUBSET SUM problem is weakly NP-complete (Karp, 1972). We will at first construct a polynomial-time reduction of SUBSET SUM to *T*-PESP-FEASIBILITY.

Definition 3.2. Let (r, c, C) be a SUBSET SUM instance as above. Define I(r, c, C) as the instance (G, T, ℓ, u) for T-PESP-FEASIBILITY as depicted in Figure 1 with $T := \sum_{i=1}^{r} c_i + 1$.

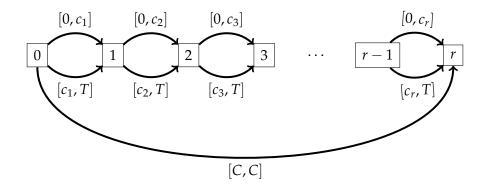

Figure 1: Instance I(r, c, C): arcs a are labeled with $[\ell_a, u_a]$, $T := \sum_{i=1}^r c_i + 1$

Lemma 3.3. The SUBSET SUM instance (r, c, C) has a solution if and only if T-PESP-FEASIBILITY has a solution on the instance I(r, c, C).

Proof. Let π be a periodic timetable for I(r,c,C). Then $[\pi_i - \pi_{i-1}]_T \in \{0,c_i\}$ holds for all $i \in \{1,\ldots,r\}$. Set

$$z_i := \begin{cases} 1 & \text{if } [\pi_i - \pi_{i-1}]_T = c_i, \\ 0 & \text{otherwise,} \end{cases} \quad i = 1, \dots, r.$$

For the arc (0, r), we then obtain

$$C = [C]_T = [\pi_r - \pi_0]_T = \left[\sum_{i=1}^r (\pi_i - \pi_{i-1})\right]_T = \left[\sum_{i=1}^r z_i c_i\right]_T = \sum_{i=1}^r z_i c_i,$$

and found a positive answer to the SUBSET SUM problem on (r, c, C). Conversely, any vector $z \in \{0, 1\}^r$ such that $c^t z = C$ yields a feasible periodic timetable π by setting

$$\pi_0 := 0$$
 and $\pi_i := \pi_{i-1} + z_i c_i$, $i = 1, ..., r$.

3.2 Treewidth

Definition 3.4 (e.g., Robertson and Seymour, 1984). Given a graph G, a *tree decomposition* of G is a pair $(\mathcal{T}, \mathcal{X})$ consisting of a tree \mathcal{T} and a family of *bags* $\mathcal{X} = (X_t)_{t \in V(\mathcal{T})}$ with $X_t \subseteq V(G)$ for each $t \in V(\mathcal{T})$ such that

- 1. $\bigcup_{t \in V(\mathcal{T})} X_t = V(G)$,
- 2. for each $a \in A(G)$, there is a bag X_t containing both endpoints of a,
- 3. for each $v \in V(G)$, the subforest of \mathcal{T} induced by $\{t \in V(\mathcal{T}) \mid v \in X_t\}$ is connected.

The *width* of a tree decomposition is $\max_{t \in (\mathcal{T})} |X_t| - 1$, and the *treewidth* of *G* is defined as the minimum possible width of a tree decomposition, i.e.,

$$\mathsf{tw}(G) := \min \left\{ \max_{t \in V(\mathcal{T})} |X_t| \, \middle| \, (\mathcal{T}, \mathcal{X}) \text{ is a tree decomposition of } G \right\} - 1.$$

This definition applies to both undirected and directed graphs, and as well to multigraphs. According to Definition 3.4. the treewidth of a graph with multiple edges equals the treewidth of the graph where all multiple edges between two vertices are replaced by a single edge. The simple connected graphs of treewidth 1 are precisely the trees.

Lemma 3.5. For any SUBSET SUM instance (r, c, C) with $r \ge 2$, the event-activity network G of the instance I(r, c, C) has treewidth 2.

Proof. The path of length *r* depicted in Figure 2, where each node is labeled with its bag, is a tree decomposition of *G*. Checking the properties of a tree decomposition is straightforward.

$$\boxed{0,1,2} \longrightarrow \boxed{0,2,3} \longrightarrow \boxed{0,3,4} \longrightarrow \cdots \longrightarrow \boxed{0,r-1,r}$$

Figure 2: An optimal tree decomposition of width 2 for the I(r, c, C) network

The maximum bag size is 3, and hence $\operatorname{tw}(G) \leq 2$. Removing one of the two arcs from i to $i+1, i=0,\ldots,r-1$, does not change the treewidth in the sense of Definition 3.4. As $r\geq 2$, this results in a simple graph containing a cycle, so that $\operatorname{tw}(G)\geq 2$.

An alternative way to see that the network G of I(r,c,C) has treewidth at most 2 is to observe that G is series-parallel (see, e.g., Bodlaender and van Antwerpen-de Fluiter, 2001, Lemma 3.4). Combining Lemma 3.3 and Lemma 3.5, we obtain:

Theorem 3.6. *T*-PESP-FEASIBILITY *is NP-complete on networks of treewidth at most 2.*

Since the transformation in the proof of Theorem 2.6 reduces the *T*-PESP-FEASIBILITY problem to *T*-RPESP-OPTIMALITY by adding antiparallel arcs, which does not alter the treewidth, we have moreover:

Theorem 3.7. *T*-RPESP-OPTIMALITY is *NP-complete on networks of treewidth at most* 2.

Remark 3.8. If simple graphs are desired, one can dispose of the parallel arcs in I(r, c, C) by subdividing any arc with bounds $[0, c_i]$ into two arcs with bounds $[0, c_i]$ and [0, 0] without affecting the feasibility of the PESP instance. Moreover, one checks that this does not increase the treewidth of I(r, c, C).

Remark 3.9. In the proof of Lemma 3.3, the period time T is chosen very large. The above NP-completeness theorems hence do not hold when T is fixed. We will give a pseudo-polynomial algorithm for T-PESP-OPTIMALITY with bounded treewidth in Section 4, showing that fixing both T and the treewidth results in a polynomial-time algorithm.

Remark 3.10. We want to remark that there has already been a paper (van Heuven van Staereling, 2018) titled *Tree Decomposition Methods for the Periodic Event Scheduling Problem*. However, the title is misleading, as the algorithm there is about finding trees *in* the network rather than considering tree decompositions in the usual sense.

3.3 Branchwidth

Definition 3.11 (Robertson and Seymour, 1991). Given a graph G, a *branch decomposition* of G is a pair (\mathcal{B}, φ) , where \mathcal{B} is a tree such that every non-leaf node has degree 3, and φ is a bijection from the leaves of \mathcal{B} to A(G). Deleting an edge e of \mathcal{B} disconnects \mathcal{B} into two subtrees and hence partitions the leaves of \mathcal{B} into two sets. Applying φ , this yields a partition $A = A_e^1 \dot{\cup} A_e^2$. This defines in turn a *vertex separator* $S_e \subseteq V$ as the set of vertices that are incident both to an edge in A_e^1 and to an edge in A_e^2 .

The *width* of a branch decomposition (\mathcal{B}, φ) is defined as $\max_{e \in E(\mathcal{B})} |S_e|$. The *branchwidth* of G is then the minimum possible width of a branch decomposition, i.e.,

$$\mathrm{bw}(G) := \min \left\{ \max_{e \in E(\mathcal{B})} |S_e| \ \middle| \ (\mathcal{B}, \varphi) \text{ is a branch decomposition of } G \right\}.$$

Treewidth and branchwidth are related as follows:

Theorem 3.12 (Robertson and Seymour, 1991, 5.1). *If* $bw(G) \ge 2$, *then*

$$bw(G) \le tw(G) + 1 \le \left\lfloor \frac{3}{2}bw(G) \right\rfloor.$$

It follows immediately that the problems *T*-PESP-FEASIBILITY and *T*-RPESP-OPTIMALITY are NP-complete on networks with branchwidth 3. We prove below that the NP-completeness is already given for branchwidth 2.

Lemma 3.13. For any SUBSET SUM instance (r, c, C), the event-activity network G of the instance I(r, c, C) has branchwidth 2.

Proof. Figure 3 shows a branch decomposition of *G*, where the leaves are labeled with the corresponding arc, and the edges are labeled with the cardinality of the corresponding vertex separator. This is clearly a branch decomposition. Checking the cardinalities of the vertex

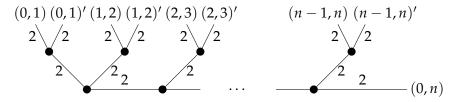

Figure 3: An optimal branch decomposition of width 2 for the I(r, c, C) network

tex separators is again straightforward, and hence $bw(G) \le 2$. The network G cannot have branchwidth 1, as in any branch decomposition, the edge incident to the leaf representing (0, r) always induces the vertex separator $\{0, r\}$ of size 2.

Theorem 3.14. *T-PESP-FEASIBILITY and T-RPESP-OPTIMALITY are NP-complete on networks with branchwidth at most 2.*

Proof. For T-PESP-FEASIBILITY, this follows from Lemma 3.3 and Lemma 3.13. Introducing anti-parallel arcs in the network of I(r,c,C) does not increase the branchwidth of 2: In the branch decomposition of the proof of Lemma 3.13, replace a leaf with a vertex of degree 3 adjacent to two new leaves corresponding to the two anti-parallel arcs. The new edges have vertex separators of size 2. Consequently, the transformation in the proof of Theorem 2.6 does not alter the branchwidth, and T-RPESP-OPTIMALITY is NP-complete on networks with branchwidth at most 2.

Another approach to prove Lemma 3.13 and Theorem 3.14 is to exploit that a graph of treewidth at most 2 has branchwidth at most 2 (combine, e.g., Bodlaender and van Antwerpende Fluiter, 2001, Lemma 3.5 with Robertson and Seymour, 1991, 4.2).

3.4 Carvingwidth

Carvingwidth is defined analogously to branchwidth, by labeling the leaves of an unrooted binary tree with the vertices of the original graph instead of the edges.

Definition 3.15 (Seymour and Thomas, 1994). Given a graph G, a *carving decomposition* of G is a pair (C, ψ) , where C is a tree such that every non-leaf node has degree 3, and ψ is a bijection from the leaves of C to V(G). Removing an edge e of C induces a partition of the leaves of C, and hence via ψ also a partition $V(G) = V_e^1 \cup V_e^2$. Let $\delta(V_e^1) = \delta(V_e^2)$ denote the set of cut edges.

The maximum cardinality of $\delta(V_e^1)$ taken over all $e \in E(\mathcal{C})$ is the *width* of (\mathcal{C}, ψ) . The *carving-width* of G is defined as

$$\mathrm{cw}(G) := \min \left\{ \max_{e \in E(\mathcal{C})} |\delta(V_e^1)| \, \middle| \, (\mathcal{C}, \psi) \text{ is a carving decomposition of } G \right\}.$$

The definition of carvingwidth applies to multigraphs as well, but in contrast to branchand treewidth, it is sensitive to multiple edges: The carvingwidth is at least the maximum vertex degree $\Delta(G)$, as $\mathrm{cw}(G) \geq \deg(v) = |\delta(v)|$ for each $v \in V(G)$. Carvingwidth is related to branchwidth as follows:

Theorem 3.16 (Nestoridis and Thilikos, 2014; Eppstein, 2018). *Let* G *be a graph with maximum vertex degree* $\Delta(G)$. *Then*

$$\max\left(\Delta(G), \left\lceil \frac{1}{2}\operatorname{bw}(G)\right\rceil\right) \leq \operatorname{cw}(G) \leq \Delta(G) \cdot \operatorname{bw}(G).$$

Theorem 3.17. *T*-PESP-FEASIBILITY *is NP-complete on networks of carvingwidth at most 3, and T-RPESP-OPTIMALITY is NP-complete on networks of carvingwidth at most 6.*

Proof. Let $r \geq 2$ and consider again an instance of the form I(r,c,C) with event-activity network G. Then $\Delta(G) = 4$, so that $\mathrm{cw}(G) \geq 4$. For all $i \in \{1,\ldots,r-1\}$, split vertex i into two new vertices i^+ and i^- , connected by a single directed arc (i^+,i^-) with bounds $\ell_{i^+,i^-} = u_{i^+,i^-} = 0$. The splitting is done in such a way that the arcs entering i are now entering i^+ , and the arcs leaving i are leaving i^- . Any periodic timetable has the same value at i^+ and i^- , so that the proof of Lemma 3.3 carries over. However, the modified graph has maximum degree 3. The carving decomposition in Figure 4, where the edges labeled with the number of cut edges, has width 3. Hence T-PESP-FEASIBILITY is NP-complete on networks of carv-

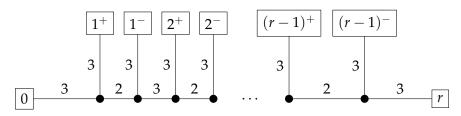

Figure 4: An optimal carving decomposition of width 3 of the modified I(r,c,C) network

ingwidth 3. As a consequence, keeping in mind the arc duplication occurring in the proof of Theorem 2.6, T-RPESP-OPTIMALITY is NP-complete for carvingwidth 6.

Remark 3.18. T-PESP-OPTIMALITY is trivial to solve on graphs G with $\mathrm{cw}(G)=1$, as then $\Delta(G)\leq 1$ by Theorem 3.16. If $\mathrm{cw}(G)=2$, then $\Delta(G)\leq 2$, so that any weakly connected component of G, seen as an undirected graph, is either a path or a cycle. T-PESP-OPTIMALITY is solvable in linear time on paths (Lemma 2.7). We will see later in Theorem 5.6 that T-PESP-OPTIMALITY admits a polynomial-time algorithm for bounded cyclomatic number, and in particular on a single cycle.

4 Dynamic Programs

The SUBSET SUM problem is weakly NP-complete and can be solved by pseudo-polynomial-time algorithms. In the following, we present two dynamic programs for *T*-PESP-OPTIMALITY running in pseudo-polynomial time for event-activity networks of bounded treewidth and branchwidth, respectively. Since *T*-PESP-OPTIMALITY comprises both *T*-PESP-FEASIBILITY and *T*-RPESP-OPTIMALITY, this implicitly gives pseudo-polynomial time algorithms for these problems as well.

4.1 PESP and Vertex Separators

The key insight for our dynamic programming approach is the following decomposition property: Let $I = (G, T, \ell, u, w)$ be a T-PESP-OPTIMALITY instance. For any partition $A(G) = A^1 \dot{\cup} A^2$, we can partition I into two subinstances I^1 resp. I^2 restricted to the activities in A^1 resp. A^2 . If y is a feasible periodic slack on I, then the restrictions y^1 resp. y^2 to I^1 resp. I^2 yield feasible periodic slacks with the property

$$\sum_{a \in A(G)} w_a y_a = \sum_{a \in A^1} w_a y_a^1 + \sum_{a \in A^2} w_a y_a^2.$$
 (3)

On the level of timetables, we obtain from a timetable π on I two timetables π^1 resp. π^2 on I^1 resp. I^2 such that π , π^1 and π^2 all coincide when restricted to the events of the vertex separator S associated to the partition of A(G) as in Definition 3.11.

Conversely, we can glue two periodic timetables π^1 and π^2 together to a timetable π on I if the restrictions to a vertex separator S satisfy $\pi^1|_S = \pi^2|_S$. For the corresponding periodic slacks then holds Equation (3).

Definition 4.1. Let $I = (G, T, \ell, u, w)$ be a T-PESP-OPTIMALITY instance, and let $S \subseteq V(G)$. For a vector $\rho \in [0, T)^S$, define $OPT(I, S, \rho)$ as the minimum weighted slack of a periodic timetable π on I when additionally $\pi|_S = \rho$ is required.

For minimum weighted slacks, the above discussion shows the following:

Lemma 4.2. Let $I = (G, T, \ell, u, w)$ be a feasible T-PESP-OPTIMALITY instance. Let $A(G) = A^1 \cup A^2$ be a partition with vertex separator S giving subinstances I^1 and I^2 of I. Then

$$OPT(I) = min\{OPT(I^1, S, \pi|_S) + OPT(I^2, S, \pi|_S) \mid \pi \text{ is a feasible periodic timetable on } I\}.$$

More generally, if additionally the timetable on $W \subseteq V(G)$ is fixed to $\rho \in [0,T)^W$, then

$$OPT(I, W, \rho) = \min\{OPT(I^1, S \cup W^1, \pi|_{S \cup W^1}) + OPT(I^2, S \cup W^2, \pi|_{S \cup W^2}) \mid \pi \text{ is a feasible periodic timetable on } I \text{ with } \pi|_W = \rho\},$$

where $W^i = W \cap V^i$ denotes the intersection of W with the set of events V^i of I^i , i = 1, 2.

4.2 A Branch Decomposition Approach

Since branch decompositions naturally encode vertex separators, we describe at first a branch-decomposition-based dynamic program for T-PESP-OPTIMALITY. Let $I = (G, T, \ell, u, w)$ be a T-PESP-OPTIMALITY instance. We assume that G is 2-edge-connected when seen as undirected graph. Let (\mathcal{B}, φ) be a branch decomposition of G with node set $V(\mathcal{B})$ and edge set $E(\mathcal{B})$. Subdivide an arbitrary edge of $E(\mathcal{B})$ and call the new node τ the *root*. Recall from Definition 3.11 that every edge $e \in E(\mathcal{B})$ corresponds to a partition $A = A_e^1 \cup A_e^2$ with vertex separator S_e . We assume that A_e^1 is the subset of activities coming from the component of $\mathcal{B} \setminus \{e\}$ not containing the root τ .

Algorithm 4.3. For each edge $e \in E(\mathcal{B})$, we compute an $|S_e|$ -dimensional table F_e having an entry for each $\pi \in \{0, ..., T-1\}^{S_e}$. The table F_e is filled by a dynamic program starting from the edges $e \in E(\mathcal{B})$ incident to leaves and with decreasing distance to the root:

1. If $e \in E(\mathcal{B})$ is incident to a leaf corresponding via φ to an activity $ij \in A(G)$, then set

$$F_e(\pi) := \begin{cases} w_{ij} [\pi_j - \pi_i - \ell_{ij}]_T & \text{if } [\pi_j - \pi_i - \ell_{ij}]_T \leq u_{ij} - \ell_{ij}, \\ \infty & \text{otherwise.} \end{cases}$$

2. If e is incident to two edges e_1 , e_2 with larger distance from the root, then set

$$F_{e}(\pi) := \min\{F_{e_1}(\pi'|_{S_{e_1}}) + F_{e_2}(\pi'|_{S_{e_2}}) \mid \pi' \in \{0, \ldots, T-1\}^{S_{e_1} \cup S_{e_2}}, \pi'|_{S_{e}} = \pi\}.$$

3. If the tables of the two edges e_1 , e_2 incident to τ have been computed, return

$$\min\{F_{e_1}(\pi) + F_{e_2}(\pi) \mid \pi \in \{0, \dots, T-1\}^{S_{e_1}}\}.$$

Lemma 4.4. Let $e \in E(\mathcal{B})$, $\pi \in \{0, ..., T-1\}^{S_e}$. Denote by I_e the subinstance of I containing precisely the activities in A_e^1 .

- 1. If $F_e(\pi) < \infty$, then $F_e(\pi) = \text{OPT}(I_e, S_e, \pi)$.
- 2. If $F_e(\pi) = \infty$, then I_e is infeasible.

Proof. Recall from Section 2 that it suffices to consider timetables with values in the discrete set $\{0, ..., T-1\}$, as ℓ and u are integer.

If e is incident to a leaf associated to an activity $ij \in A(G)$, then $A_e^1 = \{ij\}$ and $S_e = \{i,j\}$, as G is 2-edge-connected. Hence $\mathrm{OPT}(I_e, S_e, \pi)$ is the minimum weighted slack of the activity ij when the timetable at i resp. j is fixed to π_i resp. π_j . Therefore we set $F_e(\pi)$ to $w_{ij}[\pi_j - \pi_i - \ell_{ij}]_T$ if the slack $[\pi_i - \pi_i - \ell_{ij}]_T$ is feasible and otherwise to ∞ .

Otherwise, let e be adjacent to $e_1, e_2 \in E$, with e_1, e_2 having larger distance from the root than e. Then $A_e^1 = A_{e_1}^1 \cup A_{e_2}^1$ and hence $S_e \subseteq S_{e_1} \cup S_{e_2}$. Moreover, $(S_{e_1} \cup S_{e_2}) \setminus S_e$ is the vertex separator of the partition of $A_e^1 = A_{e_1}^1 \cup A_{e_2}^1$. Applying Lemma 4.2 for $W = S_e$ and $S = (S_{e_1} \cup S_{e_2}) \setminus S_e$ yields the formula in Algorithm 4.3.

Lemma 4.5. If $k = \max_{e \in E(\mathcal{B})} |S_e|$ and m = |A(G)|, then Algorithm 4.3 computes OPT(I) or decides that I is infeasible in $O(mT^{\lfloor 3k/2 \rfloor})$ time.

Proof. We first consider correctness. At the root τ with incident edges e_1 , e_2 , Algorithm 4.3 computes the tables F_{e_1} , F_{e_2} such that $F_{e_i}(\pi) = \text{OPT}(I_{e_i}, S_{e_i}, \pi)$ for all π and i = 1, 2 by Lemma 4.4. Observe that $A_{e_1}^1 = A_{e_2}^2$, $A_{e_1}^2 = A_{e_2}^1$, and $S_{e_1} = S_{e_2}$, so that by the first equation in Lemma 4.2,

$$OPT(I) = \min\{OPT(I_{e_1}, S_{e_1}, \pi) + OPT(I_{e_2}, S_{e_2}, \pi) \mid \pi \in \{0, \dots, T-1\}^V \text{ feasible timetable}\}.$$

This is precisely reflected in the third step of Algorithm 4.3, treating infeasible subinstances with infinite objective value.

Concerning running time, Step 1 can be done in $O(T^2)$ time and is called m times. Step 3 takes $O(T^k)$ time since $|S_{e_1}| \leq k$. As any node in the rooted branch decomposition has either 0 or 2 children and there are m leaves, there are m-1 edges for which Step 2 is called. Each of the $|S_e|$ table entries requires to take a minimum over $|(S_{e_1} \cup S_{e_2}) \setminus S_e|$ previously computed table entries.

We claim that

$$2|S_{e_1} \cup S_{e_2}| \le |S_{e_1}| + |S_{e_2}| + |S_{e}|.$$

If $i \in S_{e_1} \setminus S_{e_2}$, then i is adjacent to an activity $a \in A^1_{e_1}$ and $a' \notin A^1_{e_1}$. Since $A^1_{e_1}$ and $A^1_{e_2}$ are disjoint, $a \notin A^1_{e_2}$. As $i \notin S_{e_2}$, then also $a' \notin A^1_{e_2}$, and consequently $a' \notin A^1_{e} = A^1_{e_1} \cup A^1_{e_2}$. It follows that $i \in S_e$, and any such i appears hence twice in the right-hand side of the above inequality. By symmetry, the same holds for all $i \in S_{e_2} \setminus S_{e_1}$. Clearly, any $i \in S_{e_1} \cap S_{e_2}$ is counted both in $|S_{e_1}|$ and $|S_{e_2}|$. This proves the claim. The relation between the separators is also depicted in Figure 5.

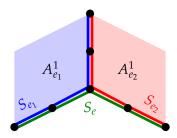

Figure 5: Relation between S_e , S_{e_1} and S_{e_2}

Since the size of any of the three vertex separators is bounded by *k*, we obtain

$$|S_e|+|(S_{e_1}\cup S_{e_2})\setminus S_e|=|S_{e_1}\cup S_{e_2}|\leq \left\lfloor rac{3k}{2}
ight
floor.$$

Thus, Step 2 accounts in total for a running time of $O(mT^{\lfloor 3k/2 \rfloor})$, and this dominates the other steps, as $k \geq 2$ since $|S_e| = 2$ for every edge e incident to a leaf of \mathcal{B} .

Having presented the core dynamic program, we now turn to the surrounding problems:

Finding an optimal branch decomposition. If $bw(G) \le k$, then there is a linear-time algorithm computing a branch decomposition of width $\le k$ (Bodlaender and Thilikos, 1997).

Computing an optimal timetable. By additional bookkeeping, we can not only compute the minimum weighted slack, but also a periodic timetable realizing this slack.

2-edge-connectedness. It is clear from the description of T-PESP-OPTIMALITY that the problem can be solved on each weakly connected component of G individually. Moreover, if one of these components is not 2-edge-connected, then the optimal periodic slack of any bridge will be zero (Borndörfer et al., 2019, §3.2). Hence one can safely assume w.l.o.g. that G is 2-edge-connected. Note that this assumption implies bw(G) \geq 2.

Fixing. If π is a feasible periodic timetable and $d \in \mathbb{R}$, then the timetable π' defined by $\pi'_i := [\pi_i + d]_T$ for all $i \in V(G)$ is feasible as well and produces the same periodic slack. In particular, in Algorithm 4.3, for all $e \in E$, one can choose an event $i \in S_e$ and then fix $\pi_i = 0$. Thus Algorithm 4.3 can be adapted to run in $O(mT^{\lfloor 3k/2 \rfloor - 1})$ time.

As a consequence, in conjunction with Lemma 2.7 and Theorem 3.14, we obtain:

Theorem 4.6. For $k \in \mathbb{N}$, there is an $O(mT^{\lfloor 3k/2 \rfloor -1})$ algorithm solving T-PESP-OPTIMALITY on event-activity networks G with m activities and $bw(G) \leq k$. In particular, if $k \geq 2$ is fixed, then T-PESP-OPTIMALITY, T-PESP-FEASIBILITY and T-RPESP-OPTIMALITY are all weakly NP-complete.

4.3 A Tree Decomposition Version

In this subsection, we develop a tree decomposition analogue of Algorithm 4.3. Let $I = (G, T, \ell, u, w)$ be a T-PESP-OPTIMALITY instance. Let $(\mathcal{T}, \mathcal{X})$ be a tree decomposition. We assume that $(\mathcal{T}, \mathcal{X})$ is *rooted*, i.e., we pick an arbitrary leaf node $\tau \in V(\mathcal{T})$ and turn \mathcal{T} into an arborescence where all edges point away from τ . Further suppose that the tree decomposition is *nice* (Kloks, 1994, Definition 13.1.15), i.e., each node $t \in V(\mathcal{T})$ with bag X_t fits into precisely one of the following categories:

- Root: $t = \tau$,
- *Leaf*: $t \neq \tau$, t has no children, and $|X_t| = 1$,
- *Introduce*: t has exactly one child u and one parent, $X_u \subseteq X_t$, and $|X_t| = |X_u| + 1$,
- *Forget*: t has exactly one child u and one parent, $X_t \subseteq X_u$, and $|X_t| = |X_u| 1$,
- *Join*: t has exactly two children u_1, u_2 and one parent, and $X_t = X_{u_1} = X_{u_2}$.

Algorithm 4.7. For each node $t \in V(\mathcal{T})$, we compute a $|X_t|$ -dimensional table D_t having an entry for each $\pi \in \{0, ..., T-1\}^{X_t}$. The table D_t is filled by the following dynamic program from the leaves to the root, depending on the role of the node t in the nice tree decomposition:

- If $t \neq \tau$ is a *leaf*, then $X_t = \{i\}$ for a single event $i \in V$. For all $\pi \in \{0, ..., T-1\}$, set $D_t(\pi) := 0$.
- If *t* is an *introduce* vertex with child *u*, then $X_t = X_u \cup \{i\}$ for some event *i*. Put

$$D_t(\pi) := D_u(\pi|_{X_u}) + \sum_{ij \in A(G): j \in X_u} w_{ij} y_{ij} + \sum_{ji \in A(G): j \in X_u} w_{ji} y_{ji},$$

where, for $ij \in A(G)$,

$$y_{ij} := \begin{cases} [\pi_j - \pi_i - \ell_{ij}]_T & \text{if } [\pi_j - \pi_i - \ell_{ij}]_T \leq u_{ij} - \ell_{ij}, \\ \infty & \text{otherwise.} \end{cases}$$

• If *t* is a *forget* vertex with child *u*, then $X_t = X_u \setminus \{i\}$ for some event *i*. Set

$$D_t(\pi) := \min\{D_u(\pi') \mid \pi' \in \{0, \dots, T-1\}^{X_u}, \pi'|_{X_t} = \pi\}.$$

• If t is a *join* vertex with children u_1 and u_2 , then $X_t = X_{u_1} = X_{u_2}$. If $D_{u_1}(\pi) < \infty$ and $D_{u_2}(\pi) < \infty$, define

$$D_t(\pi) := D_{u_1}(\pi) + D_{u_2}(\pi) - \sum_{ij \in A: i \in X_t, j \in X_t} w_{ij} [\pi_j - \pi_i - \ell_{ij}]_T$$

otherwise set $D_t(\pi) := \infty$.

• If $t = \tau$ is the *root*, then compute D_{τ} treating τ as a forget node. Return

$$\min\{D_{\tau}(\pi) \mid \pi \in \{0,\ldots,T-1\}^{X_{\tau}}\}.$$

For a node $t \in V(\mathcal{T})$, define G_t as the subnetwork of G induced by the events in the bag of X_t and the bags of all descendants of t in \mathcal{T} . Denote by I_t the corresponding T-PESP-OPTIMALITY subinstance of I.

Lemma 4.8. Let $t \in V(T)$ be a node of the tree decomposition and $\pi \in \{0, ..., T-1\}^{X_t}$.

- 1. If $S_t(\pi) < \infty$, then $S_t(\pi) = \text{OPT}(I_t, X_t, \pi)$.
- 2. If $S_t(\pi) = \infty$, then there is no feasible peridoic timetable on I_t coinciding with π on X_t .

Proof. Let $G_t = (V_t, A_t)$. If $t \neq \tau$ is a leaf, then $A_t = \emptyset$, and both statements are trivial. Introducing an event i at t with child u means that

$$V_t = V_u \cup \{i\}, \quad A_t = A_u \cup (\{ij \in A : j \in X_u\} \cup \{ji \in A : j \in X_u\}).$$

The latter is a partition of the activities of G_t whose vertex separator is contained in X_u . By Lemma 4.2, $D_t(\pi)$ must hence equal $D_u(\pi|_{X_u})$ plus the minimum weighted slack of the subinstance associated to $A_t \setminus A_u$ fixing the timetable at X_t , and the latter is precisely given by the formula in Algorithm 4.7.

When forgetting an event i at t with child u, then $G_t = G_u$. However, the timetable has to be fixed at X_t which contains one vertex less than X_u , so that we minimize over all table entries where the timetable restricted to X_u is the same.

If t is a join vertex with u_1 and u_2 as children, then $G_t = G_{u_1} \cup G_{u_2}$. We apply Lemma 4.2 to $A_t = A_{u_1} \cup (A_{u_2} \setminus A_{u_1})$ and to $A_{u_2} = (A_{u_2} \setminus A_{u_1}) \cup (A_{u_1} \cap A_{u_2})$. Note that by the connectedness property of the tree decomposition, any activity $A_{u_1} \cap A_{u_2}$ has both endpoints in $X_t = X_{u_1} = X_{u_2}$, so that X_t contains the vertex separators of both partitions. Now the minimum weighted slack on G_t is the sum of the minimum weighted slacks on G_{u_1} and G_{u_2} , subtracting the minimum weighted slack of the activities that have been counted twice, i.e., $A_{u_1} \cap A_{u_2}$. Hence the minimum weighted slack on G_t can be computed as described in Algorithm 4.7. If fixing the timetable π on X_t yields an infeasible timetable, then either $D_{u_1}(\pi)$ or $D_{u_2}(\pi)$ must have been infinite, and vice versa.

Finally, if $t = \tau$ is the root, then τ has degree one and hence has a unique child u, so that we can treat it as a forget node.

Lemma 4.9. If I is feasible, then Algorithm 4.7 returns OPT(I), and otherwise ∞ . Moreover, Algorithm 4.7 runs in $O(|V(T)|T^{k+1})$ time, where $k := \max_{t \in V(T)} |X_t| - 1$.

Proof. By Lemma 4.8, at the root τ , the table entry $D_{\tau}(\pi)$ is the minimum weighted slack on the subnetwork $G_{\tau} = G$ fixing the timetable at X_{τ} to π (or ∞). Minimizing over all entries in D_{τ} hence gives the minimum weighted slack of the T-PESP-OPTIMALITY instance (or detects infeasibility). The running time estimate is straightforward, as we need to fill each of the $|V(\mathcal{T})|$ tables with at most T^{k+1} entries and only employ summation and minimization. \square

Theorem 4.10. For $k \in \mathbb{N}$, there is an $O(nT^k)$ algorithm solving T-PESP-OPTIMALITY on event-activity networks G with n events and $\operatorname{tw}(G) \leq k$.

Proof. By Bodlaender (1996), if $\operatorname{tw}(G) \leq k$, then a tree decomposition with O(n) nodes realizing width $\operatorname{tw}(G)$ can be found in $O(f(k) \cdot n)$ time. This can be transformed into a nice tree decomposition on O(n) nodes within O(n) time (Kloks, 1994, Lemma 13.1.3). Applying Lemma 4.9 provides an $O(nT^{k+1})$ algorithm. Using the same fixing strategy as for Theorem 4.6, we obtain an $O(nT^k)$ algorithm.

Remark 4.11. The branch-decomposition based algorithm of Theorem 4.6 has a running time of $O(mT^{\lfloor 3\,\mathrm{bw}(G)/2\rfloor-1})$ time, and the tree-decomposition based one runs in $O(nT^{\mathrm{tw}(G)})$, see Theorem 4.10. By Theorem 3.12, if G is 2-edge-connected, then $nT^{\mathrm{tw}(G)} \leq mT^{\lfloor 3\,\mathrm{bw}(G)/2\rfloor-1}$, so that the tree-decomposition-based algorithm is expected to be asymptotically superior.

Remark 4.12. In terms of memory, Algorithm 4.3 with the fixing strategy needs to store at most $T^{\mathrm{bw}(G)-1}$ table entries per edge, whereas Algorithm 4.7 (with fixing) stores at most $T^{\mathrm{tw}(G)-1}$ entries per node. In both cases, at most 3 tables need to be stored at the same time, as any node in one of the decompositions has at most 2 children. Since $\mathrm{bw}(G) - 1 \leq \mathrm{tw}(G)$ if $\mathrm{bw}(G) \geq 2$, the branch-decomposition-based method potentially requires less space.

Remark 4.13. We omit a carving-decomposition-based algorithm. Bounding the carvingwidth by k means that the branchwidth is bounded by 2k according to Theorem 3.16 and we can invoke Algorithm 4.3.

5 Fixed-parameter tractable algorithms

We have already seen in Lemma 2.8 that fixing the number of events or the number of activities leads to fixed-parameter tractable algorithms for *T*-PESP-OPTIMALITY. In this section, we discuss fixed-parameter tractability by cyclomatic number, diameter, and vertex cover number. The cyclomatic number is a common measure for the difficulty of PESP instances, as it counts the number of integral variables in a cycle-based mixed integer programming formulation (Borndörfer et al., 2019). The size of a minimum vertex cover has led to fixed-parameter algorithms for several coloring problems where bounding the treewidth does still result in NP-hard problems (Fiala et al., 2011), as it is the case for the PESP family.

5.1 Cyclomatic Number

Definition 5.1. Let *G* be a graph on *n* vertices, *m* edges and *c* weakly connected components. The *cyclomatic number* of *G* is defined as $\mu(G) := m - n + c$.

Alternatively, the cyclomatic number is the dimension of the cycle space of *G*.

Lemma 5.2. *Let* G *be a graph. Then* $\mathsf{tw}(G) \leq \mu(G) + 1$.

Proof. We give a proof by induction on $\mu(G)$. If $\mu(G) = 0$, then G is a forest and therefore $\operatorname{tw}(G) = 1$.

Now let G be a graph with $\mu(G) > 0$. Then G contains a cycle and hence an edge e such that $G' := G \setminus \{e\}$ has the same number of connected components as G, and $\mu(G') = \mu(G) - 1$. By induction hypothesis, $\operatorname{tw}(G') \le \mu(G') + 1 = \mu(G)$, so that we find a tree decomposition $(\mathcal{T}, \mathcal{X})$ of G' with maximum bag size at most $\mu(G) + 1$. If there is a bag containing both endpoints of e, then $(\mathcal{T}, \mathcal{X})$ is also a valid tree decomposition for G, and so $\operatorname{tw}(G) \le \mu(G)$. Otherwise let i be an endpoint of e and add i to each bag of $(\mathcal{T}, \mathcal{X})$. This is a tree decomposition for G of width $\mu(G) + 1$, so that $\operatorname{tw}(G) \le \mu(G) + 1$.

While it is true that treewidth and branchwidth can be bounded in terms of each other (see Theorem 3.12), this does not hold for treewidth and cyclomatic number:

Lemma 5.3. For $k \geq 2$, there is a class C_k of simple connected graphs such that $\operatorname{tw}(G) \leq k$ holds for all $G \in C_k$, but for any $N \in \mathbb{N}$, there is a graph $G \in C$ with $\mu(G) \geq N$.

Proof. Let \mathcal{C} be the class of graphs G built from a finite disjoint union of cliques of size k with vertex sets V_1, \ldots, V_r together with one additional vertex v joined to each vertex from each clique. Let \mathcal{T} be a path on the vertices $\{1,\ldots,r\}$, and set $X_i:=V_i\cup\{v\}, i=1,\ldots,r$. Then $(\mathcal{T},\mathcal{X})$ is a tree decomposition of G and, as $|X_i|=k+1$, we have $\mathrm{tw}(G)\leq k$. The cyclomatic number of G is given by

$$\mu(G) = \left(r \cdot \frac{k(k-1)}{2} + rk\right) - (rk+1) + 1 = r \cdot \frac{k(k-1)}{2},$$

and for $k \ge 2$, this goes to infinity as $r \to \infty$.

Theorem 5.4. On networks where no vertex has degree 2, T-PESP-OPTIMALITY is fixed-parameter tractable when parameterized by the cyclomatic number.

Proof. Let (G, T, ℓ, u, w) be a T-PESP-OPTIMALITY instance. We can safely remove all $i \in V(G)$ with $\deg(i) = 1$, as in any optimal solution, the incident activity must have periodic slack 0. Hence we can assume that G has minimum degree 3. By the Handshaking Lemma,

$$2m = \sum_{i \in V(G)} \deg(i) \ge 3n,$$

and hence

$$\mu=m-n+c\geq \frac{n}{2}+1,$$

so that $n \le 2\mu - 2$. This means that fixing μ provides a fixed bound on the number n of events, and we conclude by Lemma 2.8.

Corollary 5.5. *T-PESP-FEASIBILITY is fixed-parameter tractable when parameterized by the cyclomatic number.*

Proof. Let (G, T, ℓ, u) be a T-PESP-FEASIBILITY instance. Remove all events of degree 1 from G, as this does neither affect feasibility nor alter the cyclomatic number. Now all degree 2 vertices of G are arranged on (undirected) paths between two vertices of degree ≥ 3 . Consider such a path from s to t with $\deg(s), \deg(t) \geq 3$, forward activities a_1, \ldots, a_r and backward activities b_1, \ldots, b_s . Delete all intermediate vertices between s and t and insert a single activity a from s to t with

$$\ell_a := \sum_{i=1}^r \ell_{a_i} - \sum_{j=1}^s u_{b_j}$$
 and $u_a := \sum_{i=1}^r u_{a_i} - \sum_{j=1}^s \ell_{b_j}$.

Clearly, if x is a feasible tension with $\ell_{a_i} \leq x \leq u_{a_i}$ and $\ell_{b_j} \leq x_{b_j} \leq u_{b_j}$ for all i and j, then also $\ell_a \leq x_a \leq u_a$ with $x_a := \sum_{i=1}^r x_{a_i} - \sum_{j=1}^s x_{b_j}$. Conversely, any x_a with $\ell_a \leq x_a \leq u_a$ can be split into feasible tensions on all a_i and b_j . Thus, this transformation preserves feasibility. Moreover, contracting vertices of degree 2 does not change the cyclomatic number, so that we can assume that G has minimum degree 3. Invoke Theorem 5.4.

Theorem 5.6. For fixed cyclomatic number μ , T-PESP-OPTIMALITY is polynomial-time solvable.

Proof. Let F be a spanning forest of G and let $\gamma_1, \ldots, \gamma_\mu$ be its fundamental cycles, seen as incidence vectors $\{-1,0,1\}^{A(G)}$. Then (e.g., Nachtigall, 1998) $x \in \mathbb{R}^{A(G)}$ is a feasible periodic tension if and only if

$$\ell \le x \le u$$
 and $\forall i \in \{1, \dots, \mu\} : \gamma_i^t x \equiv 0 \mod T$.

Decomposing $\gamma_i = \gamma_{i,+} - \gamma_{i,-}$ into positive resp. negative part $\gamma_{i,+}, \gamma_{i,-} \in \{0,1\}^{A(G)}$, the modulo constraints are equivalent to

$$\forall \in \{1,\ldots,\mu\}: \quad \gamma_i^t x = T z_i, \quad \left\lceil \frac{\gamma_{i,+}^t \ell - \gamma_{i,-}^t u}{T} \right\rceil \leq z_i \leq \left\lceil \frac{\gamma_{i,+}^t u - \gamma_{i,-}^t \ell}{T} \right\rceil, \quad z_i \in \mathbb{Z}.$$

These are the so-called *cycle inequalities* (Odijk, 1994). In particular, for each *i*, one has to check at most

$$\left| \frac{\gamma_{i,+}^t u - \gamma_{i,-}^t \ell}{T} \right| - \left\lceil \frac{\gamma_{i,+}^t \ell - \gamma_{i,-}^t u}{T} \right\rceil + 1 \le \frac{(\gamma_{i,+} + \gamma_{i,-})^t (u - \ell)}{T} + 1$$

values for z_i . Since, as in the proof of Theorem 2.6, we can assume w.l.o.g. that $u - \ell < T$, we have the estimate

$$z_i \leq |\{a \in A(G) : \gamma_{i,a} \neq 0\}| + 1 \leq n + 1,$$

as the γ_i are simple cycles and hence contain at most n vertices.

The description of the polynomial-time algorithm is now: Enumerate all $O((n+1)^{\mu})$ integral vectors (z_1, \ldots, z_{μ}) satisfying the cycle inequalities and solve the problem

Minimize
$$w^t x$$
 subject to $\ell \le x \le u$ and $\forall \in \{1, ..., \mu\} : \gamma_i^t x = Tz_i$.

This is a minimum cost network tension problem and can be solved in polynomial time by network flow approaches (Hadjiat and Maurras, 1997; Nachtigall and Opitz, 2008). Alternatively, the above minimization problem can be solved by linear programming.

It remains open whether *T*-PESP-OPTIMALITY can be solved with a fixed-parameter algorithm w.r.t. the cyclomatic number. The main problem is that the cyclomatic number does not bound the number of vertices. However, if, e.g., one additionally fixes the *diameter* of a graph, i.e., the maximum length of an undirected shortest path between two vertices, then also *T*-PESP-OPTIMALITY becomes fixed-parameter tractable:

Corollary 5.7. *T-PESP-OPTIMALITY is fixed-parameter tractable when parameterized by cyclomatic number and diameter.*

Proof. We adapt the proof of Theorem 5.6. In our final estimate of z_i , the number of activities contained in γ_i can be bounded from above by 2d if d denotes the diameter of the graph. \Box

We want to remark that fixing both cyclomatic number and diameter does *not* bound the number of vertices:

Lemma 5.8. For any $k \in \mathbb{N}$, there is an infinite class of simple connected graphs of diameter at most 2 and cyclomatic number at most k.

Proof. For $r \ge k$, let G be a star graph on r leaves. Connect k distinct pairs of leaves by an edge. Then $\mu(G) = (k+r) - (r+1) + 1 = k$ and G has diameter 2.

5.2 Vertex Cover Number

Definition 5.9. For a graph G, its *vertex cover number* vc(G) is defined as the minimum cardinality of a vertex cover of G.

Lemma 5.10 (Fiala et al., 2011, $\S 2$). Let G be a graph. Then $\mathsf{tw}(G) \leq \mathsf{vc}(G) + 1$.

The vertex cover number does neither limit the number of vertices (consider star graphs) nor the cyclomatic number (complete bipartite graphs $K_{2,q}$), but it does bound the diameter: On a simple path of length d, at least d/2 vertices have to be part of a vertex cover. It follows that fixing both cyclomatic number and vertex cover number gives a fixed-parameter algorithm for T-PESP-OPTIMALITY by Corollary 5.7. We show in the following that T-PESP-FEASIBILITY is W[1]-hard when parameterized by the vertex cover number only, so that the existence of a fixed-parameter algorithm is unlikely. It remains unclear if T-PESP-OPTIMALITY admits a polynomial-time algorithm for fixed vertex cover number.

Theorem 5.11. T-PESP-FEASIBILITY is W[1]-hard when parameterized by the vertex cover number.

Proof. We provide a fixed-parameter reduction of the LIST COLORING problem, which is known to be W[1]-hard (Fiala et al., 2011, Theorem 1). An instance consists of a graph H together with a finite list $L(v) \subseteq \mathbb{Z}_{\geq 0}$ for each $v \in V(H)$, and the task is to find a vertex coloring of H such that each vertex v is colored with a color in L(v).

Given (H, L), we construct a T-PESP-FEASIBILITY instance (G, T, ℓ, u) as follows: Define $T := \max_{v \in V(H)} L(v) + 1$. Let G be any orientation of H. For each edge of G, the corresponding activity a in A(G) obtains the bounds $\ell_a := 1$ and $u_a := T - 1$. Further add a new vertex v_0 to G. Let $v \in V(H)$ with $L(v) = \{c_1, \ldots, c_r\}$, $c_1 < \cdots < c_r$. Add r parallel activities a_1, \ldots, a_r from v_0 to v, with bounds

$$\ell_{a_i} := c_i, \quad u_{a_i} := c_{i-1} + T, \quad i = 1, \dots, r,$$

where we set $c_0 := c_r - T$. This way, we model the disjunctive constraints of choosing a color in L(v) as a PESP instance (Liebchen and Möhring, 2007, §3.3).

We claim that (H,L) has a feasible list coloring if and only if (G,T,ℓ,u) admits a feasible periodic timetable. Thus, let $\pi \in [0,T)^{V(H)}$ be a list coloring for (H,L). If $ij \in A(H)$, then $\pi_j \neq \pi_j$, so that $[\pi_j - \pi_i - 1]_T \leq T - 2$ is a feasible periodic slack. Extend π to a timetable on G by setting $\pi_{v_0} := 0$. Let $v \in V(H)$, and assume that v is colored with the j-th color from its list, i.e., $\pi_v = c_j \in L(v)$. For $i \in \{1, \ldots, r\}$, for the i-th activity a_i from v_0 to v, the periodic tension would be

$$[\pi_v - \pi_{v_0} - \ell_{a_i}]_T + \ell_{a_i} = [c_j - c_i]_T + c_i = \begin{cases} c_j & \text{if } i \leq j, \\ c_j + T & \text{if } i > j. \end{cases}$$

In the first case $c_j \le T \le c_{i-1} + T$, and in the second $c_i > c_j$ implies $c_j + T \le c_{i-1} + T$. We conclude that π is a feasible periodic timetable.

Conversely, consider a feasible periodic timetable $\pi \in [0,T)^{V(G)}$. By a shift replacing π by $[\pi - \pi_{v_0}]_T$, we can assume that $\pi_{v_0} = 0$. By restriction, using that $\pi_i \neq \pi_i$ for all $ij \in A(H)$,

 π yields a coloring of H. It remains to check that this is a feasible list coloring. The periodic tension on an activity a_i from v_0 to v must satisfy

$$[\pi_v - \pi_{v_0} - \ell_{a_i}]_T + \ell_{a_i} = [\pi_v - c_i]_T + c_i \le c_{i-1} + T$$
 for all $i \in \{1, \dots, r\}$.

Suppose that there is an index j such that $c_j \leq \pi_v < c_{j+1}$. Then the above inequality for i = j+1 means

$$\pi_v + T = [\pi_v - c_{j+1}]_T + c_{j+1} \le c_j + T$$
,

hence $\pi_v = c_j$. If $\pi_v \ge c_r$, then $\pi_v \le c_0 + T = c_r$. Finally if $\pi_v < c_1$, then $\pi_v \le c_r - T < 0$, contradicting $\pi_v \ge 0$. This shows that $\pi_v \in \{c_1, \ldots, c_r\}$, so that π is indeed a feasible list coloring.

Since all arcs in G not present in H are connected to v_0 , we obtain $vc(G) \le vc(H) + 1$. In particular, any fixed-parameter algorithm for T-PESP-FEASIBILITY yields a fixed-parameter algorithm for LIST COLORING.

6 Structure of Realistic Event-Activity Networks

In this section, we discuss the size of the so far discussed graph parameters on realistic periodic timetabling instances. We consider networks with a special structure based on line networks. This structure is the direct outcome of a typical modeling process (Nachtigall, 1998; Liebchen and Möhring, 2007; Schöbel, 2017; Pätzold et al., 2017). For example, the railway networks in the benchmarking library *PESPlib* (Goerigk, 2012) are found as subgraphs of networks with this structure. For this type of networks, we give lower and upper bounds on the branchwidth in terms of the underlying line network. We use this theoretical result to compute bounds on the branchwidth of the smallest PESPlib instance R1L1.

6.1 Line-Based Event-Activity Networks

Public transportation systems of cities, but also railway services, are typically organized in *lines*.

Definition 6.1. A *line network* (N, \mathcal{L}) is a directed multigraph N, together with a set \mathcal{L} of directed walks on G such that the arc set A(N) is the disjoint union of $A(\ell)$ over all *lines* $\ell \in \mathcal{L}$.

Line networks reflect the maps public transport companies offer for passenger information, displaying stations and lines. Depending on the precise application, lines may also constitute non-simple paths or contain cycles (e.g., London's Circle Line or Berlin's Ringbahn). In the context of line planning, we interpret a line network as a frequency-expanded line plan, i.e., some lines might have the same vertex sequence. Given a line network (N, \mathcal{L}) , construct an event-activity network G as follows:

- 1. For each line $\ell \in \mathcal{L}$ and each arc $ij \in A(\ell)$, create a *departure event* (i, ℓ, dep) and an *arrival event* (j, ℓ, arr) , and connect these by a *driving activity* $((i, \ell, \text{dep}), (j, \ell, \text{arr}))$.
- 2. For each vertex $i \in V(N)$ and each line $\ell \in \mathcal{L}$, add a *dwelling activity* $((i, \ell, arr), (i, \ell, dep))$ if both events exist.
- 3. For each vertex $i \in V(N)$ and each pair (ℓ_1, ℓ_2) of distinct lines, add a *transfer activity* $((i, \ell_1, arr), (i, \ell_2, dep))$ if both events exist.

Definition 6.2. An event-activity network G is *line-based* if it arises from a line network (N, \mathcal{L}) by the above construction. Shortly, G is *based* on (N, \mathcal{L}) .

Denote by $\deg^+(i)$ resp. $\deg^-(i)$ the number of outgoing resp. ingoing arcs at i. We summarize some straightforward structural properties of line-based networks in the following lemma:

Lemma 6.3. *Let* G *be based on* (N, \mathcal{L}) .

- 1. *G* is bipartite, the parts being the departure and arrival events, respectively.
- 2. Every departure event has a unique outgoing activity and every arrival event has a unique ingoing activity. In both cases, these are driving activities.
- 3. The driving activities in G form a perfect matching in G.
- 4. Deleting the driving activities from G and undirecting the arcs results in the disjoint union of complete bipartite graphs $K_{\deg^+(i),\deg^-(i)}$ over $i \in V(N)$.

6.2 Branchwidth of Line-Based Networks

To give bounds on the branchwidth of line-based event-activity networks, we start with a well-known result on the branchwidth of minors:

Theorem 6.4 (Robertson and Seymour, 1991, 4.1). *If* G *is a graph and* H *is a minor of* G, *then* $bw(H) \leq bw(G)$.

By Lemma 6.3, this implies that if G is based on (N, \mathcal{L}) , then

$$bw(G) \ge \max_{i \in V(N)} bw(K_{\deg^+(i),\deg^-(i)}).$$

As we did not manage to find a reference in the literature for the branchwidth of complete bipartite graphs, we give a proof here:

Lemma 6.5. *The complete bipartite graph* $K_{p,q}$ *has branchwidth* $\min(p,q)$.

Proof. Assume $p \le q$. Let P and Q denote the two parts, |P| = p, |Q| = q. The vertex separator associated to any neighborhood $\delta(w)$ for $w \in Q$ is given by P. Moreover, if $E \subsetneq \delta(w)$ is a proper subset, then the cardinality of the corresponding vertex separator is $|E| + 1 \le p$. Take any ternary tree with q leaves labeled with the vertices in Q. Then replace each leaf w by any ternary tree with p leaves, labeled by the edges in $\delta(w)$. The result is a branch decomposition of $K_{p,q}$ of width p. This shows bw($K_{p,q}$) $\le p$.

To show that $bw(K_{p,q}) \ge p$, we make use of *tangles*. That is, if we can find a collection \mathcal{T} of subsets of $E(K_{p,q})$ such that

- 1. for each $A \in \mathcal{T}$, the size of the corresponding vertex separator is at most p-1,
- 2. for each $A \subseteq E(K_{p,q})$ inducing a separator of size $\leq p-1$, either A or its complement is in \mathcal{T} ,
- 3. for any three sets $A_1, A_2, A_3 \in \mathcal{T}$, their union is not $E(K_{p,q})$,
- 4. for each $A \in \mathcal{T}$, the subgraph induced by A does not contain all vertices of $K_{p,q}$,

then bw($K_{p,q}$) $\geq p$ or $p \leq 2$ holds (Robertson and Seymour, 1991, 4.3). Clearly, bw($K_{1,q}$) = 1, as these are star graphs, and bw($K_{2,q}$) = 2, as these are series-parallel and contain cycles. Hence suppose $p \geq 3$ and define

$$\mathcal{T} := \{ A \subseteq E(K_{p,q}) \mid \text{sep}(A) \le p - 1, |V(K_{p,q}[A]) \cap P| \le p - 1, |V(K_{p,q}[A]) \cap Q| \le p - 1 \},$$

where sep(A) denotes the cardinality of the vertex separator associated to A, and $K_{p,q}[A]$ is the subgraph induced of $K_{p,q}$ by A. We check the above properties:

- 1. This is clear.
- 2. Let $A \subseteq E(K_{p,q})$ with $\operatorname{sep}(A) \le p-1$ and suppose that $K_{p,q}[A]$ contains all vertices of P. Then there must be a vertex $v \in P$ incident to some edge of A, but not contained in the separator. Hence, A must contain $\delta(v)$, and every vertex $w \in Q$ is incident to the edge $vw \in A$. Similarly, if A contains at least p vertices from Q, then it contains $\delta(w)$ for at least $|V(K_{p,q}[A]) \cap Q| (p-1)$ vertices $w \in Q$. This means if $\operatorname{sep}(A) \le p-1$ and $A \notin \mathcal{T}$, then A contains $\delta(v)$ for some $v \in P$ and $\delta(w)$ for at least q (p-1) vertices $w \in Q$. The subgraph induced by the complement of A hence does not contain v, and it also does not contain at least q (p-1) vertices of Q. Therefore the complement of A is in \mathcal{T} .
- 3. It follows by the argument in 2. that for each $A \in \mathcal{T}$, the vertex separator is given by $V(K_{p,q}[A])$. Now $K_{p,q}[A]$ is a simple bipartite graph on at most p-1 vertices. It follows that $|A| \leq (p-1)^2/4$. Now if $A_1, A_2, A_3 \in \mathcal{T}$, the cardinality of their union is at most $3(p-1)^2/4 < p^2 \leq pq = |E(K_{p,q})|$.

4. This follows as $|V(K_{p,q}[A])| \le 2p - 2 < 2p \le p + q = |V(K_{p,q})|$.

Hence we conclude $bw(K_{p,q}) = p$.

Theorem 6.6. Let G be a line-based event activity network, based on the line network (N, \mathcal{L}) . Then

$$\max_{i \in V(N)} \min(\deg^+(i), \deg^-(i)) \le \operatorname{bw}(G) \le \operatorname{cw}(N),$$

and both bounds are sharp.

Recall from Subsection 3.4 that cw(N) denotes the carvingwidth of N, and that

$$cw(N) \ge \max_{i \in V(N)} (\deg^+(i) + \deg^-(i)).$$

Speaking more intuitively, the carvingwidth is hence bounded by the maximum number of lines departing and arriving at a stop of the line network. In practice, line networks are often planar, and the carvingwidth of planar graphs can be computed in polynomial time by the ratcatcher algorithm (Seymour and Thomas, 1994).

Proof. The lower bound follows from Lemma 6.3, Theorem 6.4 and Lemma 6.5. For $r \in \mathbb{N}$, let N_r be a graph on the vertex set $\{0,1,\ldots,2r\}$, and arcs (i,0) for $i \in \{1,\ldots,r\}$ and (0,i) for $i \in \{r+1,\ldots,2r\}$. The lines are given by $\mathcal{L} := \{(i,0,i+r) \mid i \in \{1,\ldots,r\}\}$. The resulting line-based event-activity network G_r has the structure of a complete bipartite graph $K_{r,r}$ plus 2r activities connecting the $K_{r,r}$ with events of degree 1 each. It follows that

$$bw(G_r) = r = \max_{i \in V(N_r)} \min(\deg^+(i), \deg^-(i)).$$

As N_r is a star graph on 2r rays, its carvingwidth is easily determined to be 2r. Hence, we found a family of graphs for which the lower bound is sharp, and the upper bound is larger than the lower bound.

Concerning the upper bound, we first partition the activities of G: For each $i \in V(N)$, let A_i denote the set of all activities incident to some departure event at i. Then $\{A_i \mid i \in V(N)\}$ partitions A(G) because of the bipartite structure of G. For $i \in V(N)$, let $(\mathcal{B}_i, \varphi_i)$ be a branch decomposition of the subgraph of G induced by A_i . Add a root b_i to each \mathcal{B}_i by subdividing

Parameter	Value
no. of vertices	3664
no. of arcs	6385
cyclomatic number	2722
vertex cover number	1832
diameter	88
maximum degree	26
branchwidth	$\in [58,70]$
treewidth	$\in [57, 97]$
carvingwidth	$\in [29, 1820]$

Table 1: Parameters of R1L1

an arbitrary edge. Let (C, ψ) be an optimal carving decomposition of N. Attach to every leaf v of C the tree $B_{\psi(v)}$, identifying v with $b_{\psi(v)}$. This results in a branch decomposition (B, φ) of C.

Now let $e \in E(\mathcal{B})$ and let $A(G) = A_e^1 \cup A_e^2$ be the induced partition. If $e \in E(\mathcal{B}_i)$, then one of A_e^1 , A_e^2 is contained in A_i , so that the vertex separator S_e has size at most $\deg^+(i) + \deg^-(i)$: S_e contains at most all $\deg^-(i)$ arrival events at i, and every other vertex in S_e must be either a departure event or the unique arrival event following a departure event. Observe that $\deg^+(i) + \deg^-(i) \le \operatorname{cw}(N)$ due to Theorem 3.16. In the other case that $e \in E(\mathcal{C})$, there is a subset $W_e \subseteq V(G)$ such that $A_e^1 = \bigcup_{i \in W_e} A_i$. Each vertex of the vertex separator S_e is hence an arrival event at some $i \in W_e$. The set S_e is in bijection to $\delta(W_e)$ by mapping $(j, \ell, \operatorname{arr})$ to $ij \in A(\ell) \subseteq A(N)$, where $(i, \ell, \operatorname{dep})$ is the unique driving activity entering $(j, \ell, \operatorname{arr})$. Hence, as \mathcal{C} was chosen to be optimal, $|S_e| = |\delta(W_e)| \le \operatorname{cw}(N)$.

Finally, we show that the upper bound is sharp: For $r \in \mathbb{N}$, let N'_r be a directed simple cycle on r vertices. Then $\mathrm{cw}(N'_r) = 2$. The event-activity network G'_r based on N'_r is then a directed simple cycle on 2r vertices and has branchwidth 2. On the other hand, the lower bound does not equal 2, as $\max_{i \in V(N'_r)} \min(\deg^+(i), \deg^-(i)) = 1$.

6.3 Parameters of R1L1

The benchmarking library PESPlib contains 20 difficult *T*-PESP-OPTIMALITY instances, created with the LinTim toolbox with data of the German railway network (Goerigk et al., 2013). None of the instances is currently solved to proven optimality.

For the event-activity network *G* of the smallest PESPlib instance R1L1, the values of the parameters discussed in this paper are summarized in Table 1. Most of the parameters are easy to obtain, therefore we elaborate only on the width parameters.

An upper bound on branchwidth

The network G in its original shape does not satisfy the properties of Lemma 6.3. However, with small modifications, we can find a line network N such that G is a subgraph of an event-activity network based on N.

Transfer activities $a \in A(G)$ are in practice typically recognized by a large span $u_a - \ell_a$. As the period time is T = 60, we let $A_t := \{ij \in A(G) \mid u_a - \ell_a \ge 59\}$. We call any vertex i with $ij \in A_t$ for some j an arrival event, and analogously any vertex j with $ij \in A_t$ for some i is called a departure event. This is well-defined and extends to a bipartition of G into arrival resp. departure events.

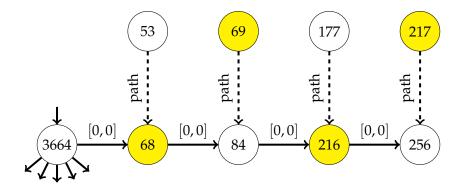

Figure 6: Removed part of R1L1, events recognized as departures are marked yellow

Now we interpret any activity from a departure to an arrival is called a driving activity. The set of driving activities is not quite a perfect matching in *G*: There are two arrival events (84 and 256) with two ingoing driving activities, and two arrival events (53 and 177) with no ingoing driving activity. This is due to four mysterious activities with lower and upper bound 0 breaking the structure at this particular spot, see Figure 6. However, the vertices 53 to 84 and 177 to 256 can be removed from *G* by sequentially deleting vertices of degree 1. Since the remaining network has branchwidth at least two, removing vertices of degree 1 has no effect on branchwidth:

Lemma 6.7. Let G be a connected graph, and let $v \in V(G)$ be a vertex of degree 1. If $bw(G \setminus \{v\}) \ge 2$, then $bw(G) = bw(G \setminus \{v\})$.

Proof. By Theorem 6.4, $bw(G \setminus \{v\}) \le bw(G)$. For the reverse inequality consider a branch decomposition (\mathcal{B}, φ) of $G \setminus \{v\}$. Since G is connected, v is adjacent to some vertex w of degree ≥ 2 . Choose an edge $e \ne \{v, w\}$ incident with w, and replace the leaf of \mathcal{B} corresponding to e by a node with the two children e and $\{v, w\}$. This is a branch decomposition of G. The size of the vertex separator corresponding to $\{v, w\}$ is 1, the size of the separator w.r.t. e is at most 2, and all other vertex separators remain unchanged. This shows $bw(G) \le bw(G \setminus \{v\})$.

With this adjustment, G has 3552 vertices and 6273 arcs. G satisfies now properties 1-3 of Lemma 6.3. Deleting the driving activities yields a disjoint union of bipartite graphs G_i , but they are not all complete. We define N now as the network obtained from G by contracting all these bipartite graphs G_i to a single vertex i. Then G is a subgraph of an event-activity network based on N, choosing, e.g., \mathcal{L} as the set of all single-arc walks. By Theorem 6.4 and Theorem 6.6, bw(G) \leq cw(N).

The network N obtained in this way is unfortunately not planar. The maximum degree in N is 62, so that $\mathrm{cw}(N) \geq 62$. To compute an upper bound, we first preprocess N by removing vertices of degree 2, as this does not alter carvingwidth (Belmonte et al., 2013, Lemma 6). We use then the Kuratowski subgraph detection algorithm implemented in the Python package networkx (Hagberg et al., 2008) to recursively remove (multi-)arcs from N until the graph becomes planar. We prefer arcs of low multiplicity, and a sequence of 20 removals of simple arcs finally yields a planar graph N'. We implemented the ratcatcher method of Robertson and Seymour to compute $\mathrm{cw}(N') = 62$ and an optimal carving decomposition. As V(N') = V(N), this is also a carving decomposition of N, but the width increases to 70. We hence conclude $\mathrm{cw}(N) \in [62,70]$ and $\mathrm{bw}(G) \leq 70$.

A lower bound on branchwidth

Since G is only realized as a subgraph of an event-activity network based on N, we cannot use Theorem 6.6 directly. Of course, it remains true that bw(G) is at least the branchwidth of the (disconnected) subgraph G' obtained by deleting the driving activities. G' is reasonably small, but there seems to be no freely available software for exact branchwidth computations. However, there are treewidth codes, and we use the algorithm by Tamaki (2019), which has been implemented for the PACE 2017 challenge on exact treewidth computations (Dell et al., 2018). It turns out that tw(G') = 20, hence $bw(G) \ge 14$.

The largest of the components of G' is a bipartite graph with maximum part size 31. If this component were complete, then Theorem 6.6 would have predicted bw(G) \geq 31.

To obtain a better bound on bw(G), we use balanced vertex separators:

Lemma 6.8 (Robertson and Seymour, 1995, 3.1). *Let* G *be a graph. Then there is a vertex separator* S *with* $|S| \leq bw(G)$ *and*

$$\max(|V^1|, |V^2|) \le \frac{2}{3}|V(G)| - \frac{1}{2}|S|,$$

where $V(G) = V^1 \cup V^2 \cup S$, and no vertex in V^1 is adjacent to a vertex in V^2 and vice versa.

We now compute a minimum cardinality vertex separator subject to the balance constraint of Lemma 6.8 by plugging in a straightforward integer program into the CPLEX¹ 12.10 solver. We do not use the full network G as input, but take a smaller network that is obtained after standard preprocessing for T-PESP-OPTIMALITY instances (Borndörfer et al., 2019, §3.2). This network is a minor of G, so that we obtain a valid bound on the branchwidth. CPLEX finds a vertex separator of cardinality 58 and is able to solve the instance to optimality. We conclude $bw(G) \geq 58$.

Treewidth and Carvingwidth

Since $bw(G) \in [58,70]$, we obtain by Theorem 3.12 that $tw(G) \in [58,104]$. As the maximum degree in R1L1 is 26, $cw(G) \in [29,1820]$ by Theorem 3.16. Determining the exact treewidth of G turns out to be computationally infeasible. We instead use TCS-Meiji (Tamaki, 2019) and FlowCutter (Hamann and Strasser, 2018), the best two submissions of the PACE 2017 challenge on heuristic treewidth computations (Dell et al., 2018), with different random seeds to obtain a better upper bound on tw(G). The best bound we could find was $tw(G) \le 97$.

Practical Implications

The instance R1L1 has a period time of T=60. It becomes clear from Table 1 that neither the dynamic programs of Section 4 nor the algorithms presented in Section 5 can be applied for solving R1L1 in practice. E.g., storing $T^{\mathrm{bw}(G)-1} \geq 60^{57}$ table entries for the branch-decomposition based algorithm 4.3 as 32-bit integers would require roughly $9 \cdot 10^{101}$ bytes of space.

7 Conclusion

The results of this paper underline that PESP is a notoriously hard problem. Although there are several primal heuristics available, the promising global approaches fail to compute provably optimal solutions: E.g., Mixed-integer programming formulations suffer from weak linear

¹https://www.ibm.com/analytics/cplex-optimizer

programming relaxations and transformations to Boolean satisfiability problems scale badly. It fits into this picture that exploiting structural parameters such as treewidth does not lead to a polynomial-time algorithm unless $P \neq NP$. Moreover, the pseudo-polynomial dynamic programs of Section 4 are only of theoretical interest. It is even unclear for tentatively large parameters as cyclomatic number and vertex cover number if T-PESP-OPTIMALITY becomes fixed-parameter tractable.

On the positive side, it has been demonstrated in (Lindner and Liebchen, 2019) that balanced edge separators lead to benefits when computing lower bounds of *T*-PESP-OPTIMALITY instances. We think that this should also carry over to vertex separators, and that good heuristic tree or branch decompositions may be useful as a source for separators in order to tackle PESP by a divide-and-conquer approach.
