## Acknowledgments

This thesis would not have been possible without the help of many excellent companions along the way.

First and foremost, I would like to thank the developers who have worked on the SCIP Optimization Suite alongside me: Timo Berthold, Leon Eifler, Gerald Gamrath, Ambros Gleixner, Leona Gottwald, Stefan Heinz, Gregor Hendel, Kati Jarck, Marco Lübbecke, Stephen Maher, Benjamin Müller, Marc Pfetsch, Daniel Rehfeldt, Franziska Schlösser, Felipe Serrano, Yuji Shinano, Stefan Vigerske, Dieter Weniger, Michael Winkler, and Jakob Witzig. You all have created a unique and stimulating atmosphere and productive working environment at the Zuse Institute Berlin (ZIB).

It has been a great honor to meet all of you and I am grateful to consider many of you close friends who I am hoping to keep connected with for many years to come. I am very pleased with the opportunity to keep working on your side as a guest at ZIB and to remain a part of this exciting community.

Most notably, I want to thank Gerald, my longstanding office mate: You have been accompanying me at ZIB since day one and I could not have wished for another person to have taken your place.

Ambros, you have been a source of inspiration and a person to look up to with your disciplined approach to research. Thank you for always finding the time to answer my questions and providing new perspectives.

Felipe, thank you for the time and energy you put into the intensive development and long-term maintenance of PySCIPOPT and the many interesting challenges we had to overcome.

All this would not have been possible without Thorsten Koch. Thank you for leading and growing our department over the years and especially for supervising this thesis. The landscape of discrete optimization-not just in Germany-would have been very different without you.

Thank you, Julian Hall, for interesting simplex discussions, for agreeing to be on my committee, and for adopting my naming suggestion concerning HiGHS-I am sure this project has a great future under your guidance and I am honored to have helped with some of the early steps and design choices.

I also want to thank Volker Mehrmann for pointing me towards ZIB after supervising
my diploma thesis. You anticipated that I was going to thrive in the fascinating field of operations research and mathematical programming.

I am grateful to Ted Ralphs and Dan Steffy for countless fruitful discussions both in-person during your visits to Berlin as well as in video calls during the pandemic and before. I left every meeting with new striking ideas and more insight-not only regarding numerical topics.
I want to say thanks to SAP for providing a challenging research project on supply network planning that has kept us on our toes for many years. Similarly, I am grateful to the MODAL Research Campus ${ }^{1}$ for providing the financial resources to support our work.
I also want to show my appreciation to Sonja Mars, my manager at Gurobi Optimization, for your continued trust and the final push to finish this dissertation.

Most of all, I want to thank my loving wife Ina for always being at my side and providing a different perspective outside of the constraints of mathematics and computer science.

[^0]
## Zusammenfassung

Die gemischt-ganzzahlige Programmierung (MILP) ist ein wichtiges Teilgebiet im Bereich der mathematischen Optimierung und kommt bei der Modellierung und Lösung einer Vielzahl von verschiedenen Anwendungsproblemen mit oft weitreichenden wirtschaftlichen Folgen zum Einsatz. Die am weitesten verbreiteten Löser für solche MILPProbleme verwenden den LP-basierten branch-and-cut-Ansatz. Hierbei wird die Ganzzahligkeitsbedingung relaxiert und das sich daraus ergebende lineare Programm (LP) dazu verwendet, die Lösungsqualität abzuschätzen und den Lösungsraum schrittweise aufzuteilen und zu verkleinern.
In dieser Arbeit vergleichen und analysieren wir verschiedene algorithmische Techniken und Software-Implementierungen, die zur Optimierung dieser LP-Relaxierungen herangezogen werden können. Wir benutzen dazu die SCIP Optimization Suite ${ }^{2}$, die es aufgrund ihrer modularen Struktur erlaubt, solche Vergleiche zwischen freien Lösern wie CLP oder SoPlex und kommerziellen Hochleistungscodes wie CPLEX, Gurobi oder XPRESS durchzuführen.
Wir untersuchen speziell, wie die von uns entwickelten Methoden LP solution polishing und persistent scaling im LP-Löser SoPLex das Verhalten von SCIP bei der Lösung von MILPs beeinflussen. Das erstere Verfahren dient dabei der Verminderung der Fraktionalität der errechneten LP-Lösungen durch Ausnutzen von multiplen optimalen Lösungen, während das zweite zu einer Verbesserung der numerischen Eigenschaften beiträgt, indem die initialen Skalierungsfaktoren über den gesamten Lösungsprozess weiterverwendet werden. Beide Verfahren erhöhen signifikant die Leistungsfähigkeit von SCIP und sind standardmäßig aktiviert.
Außerdem beinhaltet diese Abhandlung eine Übersicht über sämtliche Eigenschaften und mathematischen Techniken, die im LP-Löser SoPLex implementiert sind und diesen von anderen vergleichbaren Implementierungen des Simplex-Algorithmus abheben. Obwohl SoPlex im direkten Vergleich weniger performant ist, zeugen diese Erweiterungen vom wissenschaftlichen Fortschritt auf dem Gebiet der linearen Programmierung.

Weiterhin präsentieren wir Ergebnisse von Studien zur numerischen Stabilität von

[^1]SCIP während der unterschiedlichen Phasen des MILP-Lösens. Hierbei beleuchten wir die Stabilität aus der Perspektive des LP-Lösers und stellen mit dem von uns entwickelten Python Paket Treed ${ }^{3}$ eine neue Möglichkeit vor, wie der Suchbaum interaktiv und animiert im dreidimensionalen Raum dargestellt werden kann. Diese Visualisierungstechnik eignet sich zur anschaulichen Darstellung des MILP-Löseprozesses von SCIP und kann somit zu einem besseren Verständnis dessen beitragen.

Darüber hinaus zeigen wir die schnelle und intuitive Erarbeitung algorithmischer Prototypen auf, die mit der von uns entwickelten SCIP Optimization Suite-Erweiterung PySCIPOPT ${ }^{4}$ möglich sind. Hiermit kann mittels der anwendungsfreundlichen Programmiersprache Python auf viele interne Datenstrukturen von SCIP zugegriffen werden, um in kurzer Zeit ohne C/C++-Kenntnisse neue Ideen zu implementieren, wie wir am Beispiel von TreeD zeigen. Auch die intuitive Modellierung ganzer Optimierungsprobleme ist möglich, ohne die zugrundeliegenden Daten in eine weitere Modellierungsumgebung zu überführen.
Sämtliche Entwicklungen und Ergebnisse sind entweder bereits in die quelloffene und für nicht-kommerzielle Nutzung verfügbare SCIP Optimization Suite eingeflossen oder als separate Pakete über die Code-Plattform GitHub ${ }^{5}$ verfügbar und frei verwendbar.

[^2]
## Abstract

Mixed-integer linear programming (MILP) plays a crucial role in the field of mathematical optimization and is especially relevant for practical applications due to the broad range of problems that can be modeled in that fashion. The vast majority of MILP solvers employ the LP-based branch-and-cut approach. As the name suggests, the linear programming (LP) subproblems that need to be solved therein influence their behavior and performance significantly.
This thesis explores the impact of various LP solvers as well as LP solving techniques on the constraint integer programming framework SCIP Optimization Suite ${ }^{6}$. SCIP allows for comparisons between academic and open-source LP solvers like CLP and SoPlex, as well as commercially developed, high-end codes like CPLEX, Gurobi, and Xpress.
We investigate how the overall performance and stability of an MILP solver can be improved by new algorithmic enhancements like LP solution polishing and persistent scaling that we have implemented in the LP solver SoPlex. The former decreases the fractionality of LP solutions by selecting another vertex on the optimal hyperplane of the LP relaxation, exploiting degeneracy. The latter provides better numerical properties for the LP solver throughout the MILP solving process by preserving and extending the initial scaling factors, effectively also improving the overall performance of SCIP. Both enhancement techniques are activated by default in the SCIP Optimization Suite.
Additionally, we provide an analysis of numerical conditions in SCIP through the lens of the LP solver by comparing different measures and how these evolve during the different stages of the solving process.
A side effect of our work on this topic was the development of Treed ${ }^{7}$ : a new and convenient way of presenting the search tree interactively and animated in the threedimensional space. This visualization technique facilitates a better understanding of the MILP solving process of SCIP.

Furthermore, this thesis presents the various algorithmic techniques like the row representation and iterative refinement that are implemented in SoPlex and that distinguish the solver from other simplex-based codes. Although it is often not as per-

[^3]formant as its competitors, SoPLex demonstrates the ongoing research efforts in the field of linear programming with the simplex method.
Aside from that, we demonstrate the rapid prototyping of algorithmic ideas and modeling approaches via PYSCIPOPT ${ }^{8}$, the Python interface to the SCIP Optimization Suite. This tool allows for convenient access to SCIP's internal data structures from the user-friendly Python programming language to implement custom algorithms and extensions without any prior knowledge of SCIP's programming language C. Treed is one such example, demonstrating the use of several Python libraries on top of SCIP. PYSCIPOPT also provides an intuitive modeling layer to formulate problems directly in the code without having to utilize another modeling language or framework.
All contributions presented in this thesis are readily accessible in source code in SCIP Optimization Suite or as separate projects on the public code-sharing platform GitHub ${ }^{9}$.

## Notation

| $\mathbb{Z}$ | Set of integers |
| :---: | :---: |
| $\mathbb{N}$ | Set of non-negative integers |
| $\mathbb{R}$ | Set of real numbers |
| n | Number of variables in the problem |
| m | Number of constraints in the problem |
| $\mathcal{C}=\{1, \ldots, n\}$ | Set of problem variable indices |
| $\mathcal{R}=\{1, \ldots, m\}$ | Set of slack variable indices |
| $\mathcal{B}$ | Set of basic indices |
| $\mathcal{N}=(\mathcal{R} \cup \mathcal{C}) \backslash \mathcal{B}$ | Set of non-basic indices |
| $\mathcal{I} \subseteq \mathcal{C}$ | Set of integer variable indices |
| $A \in \mathbb{R}^{m, n}$ | Constraint matrix of the problem |
| $A^{\top}$ | Transpose of matrix $A, A^{\top} \in \mathbb{R}^{\mathrm{n}, \mathrm{m}}$ |
| $\mathrm{a}_{\text {q }}$ | qth column of $A, \mathrm{a}_{\mathrm{q}}=A . \mathrm{q}$ |
| B | Basic part of matrix $A, B=A_{\mathcal{B}}$ |
| N | Non-basic part of matrix $A, N=A_{\mathcal{N}}$ |
| LP | Linear programming problem (also refers to the problem class) |
| MILP | Mixed-integer linear programming problem (also refers to the problem class) |
| $K$ | Condition number of a square matrix, $\kappa(A)=\\|A\\| \cdot\left\\|A^{-1}\right\\|$ |
| KLP | LP condition number (see Definition 6 in Chapter 6) |

## Chapter 1

## Introduction

In all my scientific presentations that dealt with the interaction between and the influence and importance of LP solving in the context of mixed-integer linear programming (MILP), I learnt that there is a great interest in understanding this relationship or at the very least in learning something new about it. Everyone from first-year PhD students to experts with decades of experience showed interest in how SCIP behaves with various different LP solvers and what takeaways we can get from that. This topic has been fueled by numerous benchmarks comparing different LP and MILP solvers over many years conducted by Prof. Hans Mittelmann as in Figure 1.1:

Figure 1.1.: Mittelmann benchmark results on MIPLIB 2010, November 2017.
This provided plenty of motivation to put in the time and effort of investigating the impact of an LP solver in SCIP.

Prof. Thorsten Koch posed the provocative question "Why LP does not matter for MILP" and motivated us to dive deep into investigating why a performance increase of an LP code often does not seem to affect the respective MILP performance accordingly. This is by no means a SCIP-specific question: The LP performance improvements of new versions of commercial solvers may not carry over to the respective MILP benchmarks. It takes more than just plugging a fast LP solver into SCIP to get a decent MILP solver.

Nevertheless, implementing new and improved LP techniques remains important and can significantly impact how an MILP is solved. In Chapter 3 we present several

## 1. Introduction

such examples, ranging from more straightforward ideas like a stable sum implementation to improve the accuracy of long summations to more involved concepts like the bound flipping ratio test or the row representation for the simplex algorithm.

A technique that is mostly relevant for solving LP relaxations in the MILP context but still entirely implemented within the domain of the simplex solver SoPLEX is LP solution polishing (Chapter 5).

Numerics play an important role both in LP and MILP solving and may decide whether an instance can be solved correctly or not. In Chapter 6 we explore the numerical features during MILP solving from the perspective of the underlying LP solver. This is guided mainly by inspecting condition numbers of matrices that occur during the solving process. One goal of this thesis is to collect and share this information and to investigate some of the folklore around LP and MILP numerics.

In summary, this work puts a focal lens on linear programming in MILP solving-quite literally, even, as we demonstrate with our LP-based visualization package TreeD in Section 4.8. This interactive visualization technique projects the LP relaxations encountered while traversing the branch-and-cut tree into a 3-dimensional space.

### 1.1. Contributions and Publications

Our work is mainly based on the MINLP solver framework SCIP Optimization Suite, most notably including the LP solver SoPLEX and the constraint integer programming solver SCIP. While writing this thesis, we developed PySCIPOPT ${ }^{1}$ (Maher, Miltenberger, et al., 2016), providing an interface to SCIP from the Python programming language. This tool allows for rapid prototyping of new algorithmic ideas as well as analysis and manipulation of internal solver data using Python. We present details about the core concepts of the implementation and performance comparisons with SCIP's C API in Chapter 2.

Using PySCIPOPT, we developed an application named Treed² (Miltenberger, 2021b), a novel 3D-visualization tool for branch-and-cut trees to provide a new perspective and further insight on how an individual instance is solved by SCIP. Treed also allows for convenient data collection and is used to conduct many of the numerical experiments presented in this thesis. See Section 4.8 for a description of the approach and further details.

LP performance improvements like exploitation of sparse data structures and the bound flipping ratio test discussed in Section 3.5 and Section 3.4 have already been presented in Gamrath, Gleixner, et al. (2019) in the context of solving challenging realworld problem instances (both LP and MILP) originating from supply chain optimization models.

Cao, Gleixner, and Miltenberger (2016) discuss the benefits and disadvantages of different solvers and solver techniques for dealing with difficult LP models in the energy and electricity markets. Such benchmarks remain of high interest in the optimization

[^5]community. Prof. Hans Mittelmann ${ }^{3}$ dedicates a lot of time, effort, and computing resources to provide up-to-date results online ${ }^{4}$ for a large variety of solvers covering a wide field of disciplines beyond LP and MILP. We created a web service ${ }^{5}$ that takes these raw performance numbers and individual log files and presents them in an interactive and more intuitive way to make them more accessible to a wider range of interested users. This project is presented in Appendix A.
The results of Chapter 6 are partly published in Miltenberger, Ralphs, and Steffy (2018). We investigate numerical features during the MILP solving process and what we can learn from this.

Furthermore, many smaller features and performance and stability improvements have been implemented in both SCIP and SoPLex during the development of this thesis and have been published in the different SCIP Optimization Suite reports for version 3.2 (Gamrath, Fischer, et al., 2016), version 4.0 (Maher, Fischer, et al., 2017), version 5.0 (Gleixner, Eifler, et al., 2017), version 6.0 (Gleixner, Bastubbe, et al., 2018), and version 7.0 (Gamrath, Anderson, et al., 2020). We discuss these in Chapter 3.
Two other technical contributions are the transition to the modern version control system git ${ }^{6}$ from the aging CVS and the introduction of the cross-platform build system CMake $^{7}$ that facilitates the creation of user-friendly installer packages and has further improved the usability and distribution of the SCIP Optimization Suite. We want to mention this here, because the accessibility of community-driven and open source software development is an often overlooked aspect in academia.
Finally, we want to mention the development of a new LP interface between SCIP and SoPLex that replaces the legacy one and facilitates several new features and algorithmic developments such as persistent scaling (Section 3.7) and LP solution polishing (Chapter 5).

### 1.2. Linear and Mixed-Integer Linear Programming

In 2012, a feature story of the NewScientist magazine ${ }^{8}$ called the Simplex method "The algorithm that runs the world". This perfectly visualizes the impact on real-world applications Linear and Mixed-Integer Linear Programming and especially the simplex method have.
The simplex algorithm is among the top 10 algorithms of the $20^{\text {th }}$ century (Cipra, 2000) and it's very likely to stay among the most used algorithms for the foreseeable future.

In mathematical notation a mixed-integer linear programming problem (MILP) can be formalized in the following way:

[^6]\[

$$
\begin{align*}
\min & c^{\top} x \\
\text { s.t. } & A x \leq b  \tag{1.1}\\
& l \leq x \leq \mathfrak{u} \\
& x_{\mathfrak{j}} \in \mathbb{Z} \quad \forall j \in \mathcal{I},
\end{align*}
$$
\]

If the set $\mathcal{I}$ is empty, that is, if there are only continuous variables, problem (1.1) reduces to a linear programming problem (LP):

$$
\begin{align*}
\min & c^{\top} x \\
\text { s.t. } & A x \leq b  \tag{1.2}\\
& l \leq x \leq u
\end{align*}
$$

There are also several other problem classes that can be distinguished: Binary optimization problems only allow variables to be either 0 or 1, while mixed-binary problems may also contain continuous variables. A problem that only consists of integer variables is called an integer programming problem or IP. For most aspects of this thesis, though, the general distinction between LP and MILP is sufficient. It should be noted that these abbreviations are synonymous for both the problem class and the specific problem instance.

With the growing popularity and applicability of mixed-integer non-linear programming, or MINLP, people are more frequently using the term MIP or mixed-integer optimization (MIO) also to encompass non-linear models. We will explicitly mention it whenever we are referring to non-linear problems and will otherwise restrict ourselves to linear optimization, that is, MILP problems.

### 1.2.1. History and Impact

At the turn of the $21^{\text {st }}$ century, Bixby, Fenelon, et al. (2000) reported how solving techniques for MILPs have evolved over the last decades. Solvers have become reliable and performant enough to deal with all kinds of general problems in the field of operations research and combinatorial optimization. The paper provides computational results using the CPLEX solver and gives an overview of the implementational techniques-many of which still being state-of-the-art today.
About a decade later, Achterberg and Wunderling (2013) analyzed the progress since then and we recommend this paper for readers interested in the evolution of algorithmic and mathematical ideas developed for high-performance MILP solvers.
Cao, Gleixner, and Miltenberger (2016) showed how we can utilize existing methods better via parameter tuning to achieve improved solving times on selected model instances from the energy and power sector.

Pushing performance to solve harder and larger models both for general blackbox and specialized applications has always been the driving force of LP and MILP development. It is worth noting that the most advanced codes available today are actually able to handle general purpose models and the range of model types is ever
increasing. Still, there are also specialized implementations, for example CONCORDE ${ }^{9}$ to tackle the Traveling Salesman Problem (TSP) better than any other solver. We refer to the excellent book by Cook (2011) for further information about this particular subclass of mathematical optimization problems.
Most recently, new exciting advancements using quantum computing (Nannicini, 2021) and machine learning (Nair et al., 2020) open new doors for further progress.

The area of mathematical optimization is fast-moving and interesting because it is useful for practical applications, can be challenging and demanding from a computational perspective, and still provides lots of open academic research questions.

### 1.3. LP Solving Approaches and Duality Theory

The early history of linear programming starts with Fourier (1827), who introduces a technique later called the Fourier-Motzkin elimination after its rediscovery by Motzkin (1936). While this algorithm was designed to solve the feasibility problem for a set of inequalities, it can also integrate an objective function that is to be minimized or maximized.

In 1947, George Dantzig invented the simplex algorithm (see Dantzig (1987) for a retrospective view). This method is now called primal simplex and has since been refined and improved multiple times. One of the most notable advancements are arguably the dual simplex method by Beale (1954) and Lemke (1954) and the first ideas to avoid explicit matrix inversion (Dantzig and Orchard-Hays, 1954) in 1954.
From a theoretical perspective the simplex method is not an efficient method as it has exponential run time, that is, the number of necessary iterations with respect to the input size is not bounded by a polynomial term. Typically, such algorithms are frowned upon because they are deemed impractical for solving real-world problems. Khachiyan (1979) introduces the ellipsoid method which stands as the first method to solve linear programming problems in polynomial time. Despite this theoretical advantage, it could not outperform the simplex method on practical problems. This changed when Karmarkar (1984) proposed the interior point method-a polynomialtime algorithm that improved the theoretical run time of the ellipsoid method and could also solve real-world LPs in a competitive time. Soon after, the primal-dual interior point method by Kojima, Mizuno, and Yoshise (1989) became the basis for state-of-the-art interior point implementations and is often faster than simplex-type methods.
Bixby (2012) provides a comprehensive coverage of the history of linear and integer optimization including corresponding implementations and is highly recommended for further reading.
Since the simplex method and the interior point algorithm are the two fundamental procedures to solve real-world linear optimization problems, we want to explain their ideas and highlight their differences. We will only provide a short introduction to

[^7]
## 1. Introduction

these methods and would like to refer to Schrijver (1986) and Vanderbei (1996) for an in-depth description and details about the underlying mathematical ideas.

The notion of duality is too important and too substantial to omit, so we will first introduce this concept before describing the solving methods.

### 1.3.1. Duality

We want to illustrate duality using the famous diet problem (see Dantzig (1990) for an interesting story about the beginnings of the simplex method). Recall the standard LP from above:

$$
\begin{align*}
\min & c^{\top} x \\
\text { s.t. } & A x \geq b  \tag{1.3}\\
& x \geq 0
\end{align*}
$$

Now, let the $x$ variables symbolize amounts of various foods (measured in some suitable units), while the constraints model the nutrient requirements of a specific diet plan:

$$
\begin{aligned}
& x=\left\{x_{\text {apple }}, x_{\text {potato }}, x_{\text {cereal }}, \ldots\right\} \\
& \left.b=\left\{b_{\text {protein }}, b_{\text {fat }}, b_{\text {sugar }}, \ldots\right\}\right\}
\end{aligned}
$$

Each constraint's coefficients represent the amount of a specific nutrient like carbohydrates, fat, sugar, etc., in one unit of that food item:

$$
0.3 x_{\text {apple }}+1.9 x_{\text {potato }}+4.5 x_{\text {cereal }}+\cdots \geq b_{\text {protein }}
$$

Finally, the objective is to minimize the cost of the diet, hence, the c values specify the price of a single unit of each food item. Such diet problems have actually been among the first linear programming models to be investigated. Their practicality was likely very limited due to the lack of variety and they are mostly interesting from a theoretical point of view.
We can form the corresponding dual LP as follows:

$$
\begin{align*}
\max & b^{\top} y \\
\text { s.t. } & A^{\top} y \leq c  \tag{1.4}\\
& y \geq 0
\end{align*}
$$

In this dual version, the variables $y$ are used to model prices for nutrient supplements:

$$
y=\left\{y_{\text {protein }}, y_{\text {fat }}, y_{\text {sugar }}, \ldots\right\}
$$

These supplements must be cheaper than the actual food items, so the right hand side of the constraints is $c$ and the constraint matrix is transposed to model the nutrient distribution of a single food item in each row:

| primal: $\min c^{\top} x$ | dual: $\max b^{\top} y$ |
| :--- | :--- |
| ith constraint $A_{i .} x \leq b_{i}$ | ith variable $y_{i} \leq 0$ |
| ith constraint $A_{i .} x \geq b_{i}$ | ith variable $y_{i} \geq 0$ |
| ith constraint $A_{i .} x=b_{i}$ | ith variable $y_{i}$ free |
| jth variable $x_{j} \geq 0$ | jth constraint $y^{\top} A_{. j} \leq c_{j}$ |
| jth variable $x_{j} \leq 0$ | jth constraint $y^{\top} A_{. j} \geq c_{j}$ |
| jth variable $x_{j}$ free | jth constraint $y^{\top} A_{. j}=c_{j}$ |

Table 1.1.: LP dualization formulas

$$
0.3 y_{\text {protein }}+0.2 y_{\text {fat }}+10.4 y_{\text {sugar }}+\cdots \leq c_{\text {apple }}
$$

The objective is now to maximize the profit of selling these supplements according to the nutrient demand of the chosen diet.

In this example, the optimum represents a cost equilibrium between consuming regular food and relying only on food supplements. The dual variables $y$ are also referred to as shadow prices.
With this illustrative example, we hope to make the concept of duality more tangible. Table 1.1 states how to transform an LP into its dual form considering different variations of constraint senses and variable bounds.
There are several important aspects of this duality that come in handy to work with LPs.

Lemma 1 (Weak duality). If $\check{x}$ is a feasible solution to the $L P \max _{x \geq 0}\left\{c^{\top} x \mid A x \leq b\right\}$ and $\check{y}$ is a feasible solution to the dual $L P \min _{y \geq 0}\left\{b^{\top} y \mid A^{\top} y \geq c\right\}$, then

$$
c^{\top} \check{x} \leq b^{\top} \check{y} .
$$

Proof. This lemma follows directly from the feasibility conditions for $\check{x}$ and $\check{y}$ :

$$
\begin{align*}
A \check{x} \leq b & \Rightarrow \check{y}^{\top} A \tilde{x} \leq \check{y}^{\top} b \\
A^{\top} \check{y} \geq c \Leftrightarrow \check{y}^{\top} A \geq c^{\top} & \Rightarrow \check{y}^{\top} A \check{x} \geq c^{\top} \check{x} \tag{1.5}
\end{align*}
$$

The two inequalities are preserved after multiplication with $\check{x}$ and $\check{y}$, respectively, because of the nonnegativity conditions $\check{x} \geq 0$ and $\check{y} \geq 0$, resulting in the desired statement $c^{\top} \check{x} \leq \check{y}^{\top} A \check{x} \leq b^{\top} \check{y}$.

Please note that we interchanged the terms primal and dual for the diet example above because the primary formulation is usually referred to as primal problem. Most textbooks use the definition from Lemma 1. Both variants are equivalent since the dualizing the dual LP again yields the original primal problem.

An immediate implication from weak duality is that as soon as equality is attained, that is, $c^{\top} \check{x}=b^{\top} \check{y}$, both solutions $\check{x}$ and $\check{y}$ are optimal for their respective problemsany further improvement according to their objective functions would violate the weak duality condition.

The fundamental theorem of linear programming is called the duality theorem:
Theorem 1 (Duality theorem).

1. If both primal and dual LPs have feasible solutions, then they also have an optimal solution and the objective values of both optimal solutions coincide.
2. If one of the problems is unbounded, then the other has no feasible solution.
3. If one of the problems has no feasible solution, then the other problem is either unbounded or infeasible.

Here is a small example to demonstrate the existence of an LP that is infeasible in its primal form as well as in its dual:

| max | $2 x_{1}-x_{2}$ | min | $y_{1}-2 y_{2}$ |
| :---: | :---: | :---: | :---: |
| s.t. | $x_{1}-x_{2} \leq 1$ | s.t. | $y_{1}-y_{2} \geq 2$ |
|  | $-x_{1}+x_{2} \leq-2$ |  | $-y_{1}+y_{2} \geq-1$ |
|  | $x \geq 0$ |  | $y \geq 0$ |

The infeasibility can be seen by adding up both constraints: The primal system on the left then reduces to $0 \leq-1$ while the dual reveals $0 \geq 1$.

For the proof of Theorem 1, we refer to the literature on LP theory, for example Vanderbei (1996) or Schrijver (1986).

Another important result from duality theory is Farkas' lemma (Farkas, 1902):
Lemma 2 (Farkas' lemma). For given $A \in \mathbb{R}^{n, m}$ and $b \in \mathbb{R}^{m}$ exactly one of the following statements is true:

1. There is $x \in \mathbb{R}^{n}$ with $A x=b$ and $x \geq 0$.
2. There is $y \in \mathbb{R}^{m}$ with $A^{\top} y \geq 0$ and $b^{\top} y<0$.

It is fairly easy to see that both statements cannot be true at the same time:

$$
A^{\top} y \geq 0 \stackrel{x \geq 0}{\Rightarrow} x^{\top} A^{\top} y \geq 0 \Rightarrow b^{\top} y \geq 0 \text { contradicting } b^{\top} y<0
$$

Figure 1.2 provides an intuitive geometrical interpretation of Lemma 2.
Lemma 2 actually provides a proof of infeasibility for LPs in form of the vector $y$ that is also commonly referred to as dual ray. This ray is used to derive further implications when solving MILPs and coming across an infeasible node LP. This process is called conflict analysis and can help to speed up the solution process, see Witzig, Berthold, and Heinz, 2019 for a recent overview.

Figure 1.2.: The condition $A x=b$ translates to $b=\sum_{i=1}^{n} x_{i} A_{. i}$ for $x \geq 0$, that is, on the left, $b$ is within the cone defined by the columns of $A$, hence, feasible. In the right illustration, $b$ is outside the feasible region and $b^{\top} y<0$ while $y^{\top} A_{. i} \geq 0$. Recall that $b^{\top} y=\|b\|\|y\| \cos \alpha$, so for non-zero vectors $b$ and $y$ the angle $\alpha$ between them has to be obtuse to satisfy $b^{\top} y<0$. The dotted hyperplane $y^{\top} z=0$ separates $b$ from the cone.

### 1.3.2. Interior Point Method

Unlike simplex-type methods that proceed along the extreme points on the boundary of the feasible region, the interior point method or barrier algorithm strictly moves within the feasible set and converges towards the optimum.
For completeness and because of its mathematical elegance, we want to sketch the general idea of an interior point method.

Let $\min _{x \geq 0}\left\{c^{\top} x \mid A x=b\right\}$ be the LP to be solved. The constraints and variable bounds can be combined with the objective function to get the unconstrained Lagrangian problem

$$
\mathcal{L}_{p}(x, y)=c^{\top} x-\mu \sum_{j=1}^{n} \log \left(x_{j}\right)-y^{\top}(A x-b)
$$

Here, $\mu>0$, the so-called barrier parameter controls the influence of the logarithmic term. The smaller $\mu$ gets, the more we allow the $x$ variables to approach zero when minimizing $\mathcal{L}_{\mathrm{p}}(x, y)$. We can apply the same transformation on the dual LP $\max _{s \geq 0}\left\{b^{\top} y \mid A^{\top} y+s=c\right\}$ :

$$
\mathcal{L}_{d}(x, y, s)=b^{\top} y+\mu \sum_{j=1}^{n} \log \left(s_{j}\right)-x^{\top}\left(A^{\top} y+s-c\right)
$$

Minimizing or maximizing these $\mathcal{L}$ functions requires finding a point where their derivatives reach zero. This is equivalent to these conditions:

$$
\begin{align*}
A x=b, & & x \geq 0 \\
A^{\top} y+s=c, & & s \geq 0  \tag{1.6}\\
x_{j} s_{j}=\mu, & & \forall j \in\{1, \ldots, n\}
\end{align*}
$$

These are relaxed Karush-Kuhn-Tucker or KKT conditions (Kuhn and Tucker, 1951), which require $\mu$ to be zero in their original form.

## 1. Introduction

The main idea of IPM is now to find a starting point and then successively reduce $\mu$ until the iterates are sufficiently close to optimality. This is carried out via solving a sequence of systems of linear equations of this type:

$$
\left[\begin{array}{ccc}
A & 0 & 0 \\
0 & A^{\top} & I \\
S_{k} & 0 & X_{k}
\end{array}\right]\left[\begin{array}{l}
\Delta x_{k} \\
\Delta y_{k} \\
\Delta s_{k}
\end{array}\right]=\left[\begin{array}{c}
r_{x} \\
r_{y} \\
r_{s}
\end{array}\right]
$$

Here, $X_{k}$ and $S_{k}$ are just diagonal matrices consisting of the values of $x_{k}$ and $s_{k}$ respectively, which correspond to the current iterates at step $k$. The actual right-hand sides depend on which variant of IPM is used-see Mehrotra (1992) for a description of the popular and well-established predictor-corrector method. The most important aspect of these equations is that they can be reduced to this so-called normal equation:

$$
\begin{equation*}
A S_{k}^{-1} X_{k} A^{\top} \Delta y_{k}=r_{x}-A S_{k}^{-1} r_{s}+A S_{k}^{-1} X_{k} r_{x} \tag{1.7}
\end{equation*}
$$

Since both $S_{k}^{-1}$ and $X_{k}$ are diagonal, the constraint matrix of equation 1.7 is a normal matrix, that is, a symmetric positive semi-definite matrix that is suitable to be decomposed using the Cholesky factorization (Mészáros, 2005). The structure of this matrix remains unchanged throughout the solving process with only $X_{k}$ and $S_{k}$ varying so an initial symbolic factorization and the sparsity structure can be preserved. This is a major difference to simplex methods as we are going to see later.
Barrier methods are generally more susceptible to numerical issues and have a higher tendency of breaking down and not converging to optimality compared to simplex methods. On the other hand, they can also solve very large LP problems within a small number of iterations-for state-of-the-art solvers typically less than 200-and can make use of multi-threaded processor architectures to further improve the solving times. See Figure 4.3 for a comparison between the barrier and simplex methods when solving MILPs with SCIP. The memory requirement of the barrier method is a lot higher compared to simplex methods, especially when the instance has an unfavorable matrix structure leading to a very dense Cholesky factorization.
Another important aspect of IPM is its ability to also deal with non-linear continuous optimization problems. Convex problems can be solved to optimality while for nonconvex problems they can find a local optimum. This feature makes IPMs an integral part of mixed-integer non-linear programming solvers because they can often provide better bounds than a linear relaxation could (Vigerske and Gleixner, 2018).

### 1.3.3. Simplex Algorithm

The simplex algorithm is built around the concept of a basis. This basis identifies one of the vertices of the polyhedron defined by the constraints $A_{i}$. and the variable bounds of the LP. Since there is always an optimal vertex solution, there also exists an associated optimal basis. It goes without saying that this holds true only if there exists an optimal solution in the first place. Please also note that there may be more
than one optimal basis. See Definition 1 in Chapter 3 for a precise description and more details.

Geometrically speaking, from one iteration to the next, the simplex method modifies the basis in a way that resembles moving from the current vertex to a neighboring one. The direction of movement is chosen to improve the value of the objective function $c^{\top} x$ until no further progress can be made-we have arrived at the optimum.

There are two main variants of simplex methods: a primal and a dual one.

The primal simplex always preserves primal feasibility on its path to optimality. The dual simplex, on the other hand, moves along the dual feasible vertices that lie outside the primal feasible region. This can be seen as moving on the optimal side of the polyhedron until the boundary of the feasible region is reached.

The dual simplex method is equivalent to applying the primal simplex to the dual version of the original LP. There are some seemingly minor differences, though, that are responsible for the typically observed superiority of the dual simplex. We will highlight these in Chapter 3. See Algorithm 1.1 and Algorithm 1.2 for a side-by-side comparison of the two simplex methods. We want to point out that the two vectors $\hat{a}_{q}=B^{-1} A_{\text {. }}$ and $\hat{a}_{p}^{\top}=\left(B^{-1} N\right)_{p}$. are of different dimensions and refer to a column $q$ and a row $p$ of the simplex tableau matrix $B^{-1} A$. This slight abuse of notation allows for a more intuitive description of the algorithm and also stresses that the value $\hat{\mathrm{a}}_{\mathrm{pq}}=$ $\hat{\mathrm{a}}_{\mathrm{q}_{\mathrm{p}}}=\hat{\mathfrak{a}}_{\mathrm{p}_{\mathrm{q}}}^{\top}$ appears in both vectors.

To start the procedure we always need a primal feasible basis in case of the primal simplex and a dual feasible basis in case of the dual simplex. We highlight one way how to generate such a starting basis in Section 3.3.

The simplex algorithm is a myopic method in a way that it always only regards the local neighborhood for finding the next step direction towards optimality. There are different ways to decide where to go next from the current basis and this step of the algorithm is commonly referred to as pricing. We explain some of the well-known pricing alternatives in Section 3.5. One can say that this step is the most significant one and provides the greatest amount of freedom. Therefore, it is also the decisive factor in the total number of iterations required to reach optimality.

With its use of the basis the simplex algorithm also inhibits some elegant and convenient discrete features. In Section 3.9 we show how an exact solution can be computed in an iterative, yet efficient way. Koch (2004b) uses the basis as a fundamental tool to proof optimality of the NETLIB LP test set.

Figure 1.3.: Schematic of the solving processes of simplex and interior point methods. The left picture shows the simplex path along the border of the feasible region while the right image depicts the interior point or barrier method's central path through the interior of the feasible region.

### 1.3.4. SoPlex

SoPLex is an implementation of the revised primal and dual simplex algorithms and combines several defining features not present in other solvers. It is a very mature code base that has been in use in the academic world (Koch, 2004b) as well as in industrial projects for more than two decades. Thorsten Koch prepared the initial public version of the code and many other researchers mostly from the Zuse Institute Berlin (ZIB) have been passing the torch to keep the solver updated and maintained over the years until the present day.
The name of the code is an abbreviation for sequential object-oriented simplex hinting at the object-oriented programming paradigm of $\mathrm{C}++$ that became very popular during the 1990s. The two major contributions in its first publication by Wunderling (1996), were shared and distributed memory parallelization schemes (called SMoPLEX and DoPLEX, respectively) as well as the use of either a column or a row representation of the simplex method. While the former is unfortunately lost in time, leaving SoPLEX to be a sequential code, the twofold basis representation is still actively maintained and put to good use to gain performance improvements (see Maher, Fischer, et al., 2017). This feature is described in more detail in Section 3.2. Another important aspect that distinguished SoPLex from most other LP solvers is its exact solving capabilities using rational arithmetic and iterative refinement as laid out by Gleixner (2015). We will present two other features that are especially useful within the branch-and-bound approach to solve MILPs, namely LP solution polishing (see Chapter 5) and the preservation of scaling factors throughout the solving process as described in Section 3.7.

SoPlex is discussed in detail in Chapter 3.

### 1.3.5. Choosing the Method

We will further discuss which LP solving method-simplex or interior point-to use in Chapter 4 for solving MILPs. Choosing the fastest method even for solving just an isolated LP is a difficult question and it is still unclear how to answer it analytically. From a computational perspective, whenever enough cores are available on the computing hardware, the pragmatic way of solving or rather avoiding this question is to simply run all the different methods in parallel. This is typically conducted in a concurrent fashion, that is, the method that finishes first, concludes the optimization and is deemed the winner.

Unfortunately, this strategy will always be slower than selecting the fastest method to run independently. This is mostly due to side effects on cache and memory bandwidth and simply more work to be done by the processor and the operating system. So, ideally, we would like to avoid this overhead and be able to figure out the fastest method depending on certain problem data characteristics. There are a number of heuristic methods that try to make an educated guess but are not always successful. The most commonly used deciding metric is the sheer size of the model instance, because with growing dimensions, the interior point method is increasingly likely to

## 1. Introduction

beat the simplex method. Recalling the way the two approaches work, this also appears apparent when considering the growing number of potential vertices the simplex method may have to traverse. The interior point method on the other hand is less affected by this increasingly complex geometry.

Still, to avoid choosing the slower method, either the concurrent approach or manual tuning for similar models is utilized in practice. When a basic solution is needed, the choice becomes even harder: Then, the interior point method's solution requires the application of a simplex-like procedure called crossover (Megiddo, 1991), effectively employing both methods. Such a basic solution also has the added benefit of a typically smaller support, that is, fewer variables have a non-zero value in the solution. This makes it also attractive for use cases that do not utilize the basis information.

Again, this demonstrates that despite its age, there are still unsolved problems and open questions in the research area of linear programming.

### 1.4. MILP Solving Approaches

Since MILP solving is $\mathcal{N} \mathcal{P}$-hard there are naturally several more or less efficient and suitable solving approaches. In case the optimal solution or a proof of optimality are not necessarily required, one may choose a heuristic-based method to produce a feasible and hopefully acceptable solution as quickly as possible. We do not further discuss such inexact methods because they are fundamentally different from the exact approaches that can provide a proof of optimality together with the solution. If the problem class is known beforehand, for example traveling salesman problems (Applegate et al., 2006) or max-flow problems (Dantzig and Fulkerson, 2003), certain specialized techniques from the field of combinatorial optimization can be employed with very good results.

For many application areas, though, it is required to provide a proven optimal solution or at the very least a reliable measure for how much a feasible solution might still be improved upon. Furthermore, most applications do not revolve around the solution of a pure combinatorial problem but are modeled as general mixed-integer linear optimization problems. This is also the scenario we are regarding in this thesis.

The most popular and probably most investigated solving approach is the LP-based branch-and-bound method. It is extended by various cutting plane techniques, primal heuristics, presolving reductions and a variety of other methods-commonly referred to as "bag of tricks". This culminates into a powerful solver that is able to tackle many problems from both academic as well as industrial background efficiently, despite the daunting complexity. Several such solvers are currently developed both by commercial vendors (for example CPLEX ${ }^{10}$, GUROBI ${ }^{11}$, XPRESS $^{12}$ ) and with an academic

[^8]background (like CBC ${ }^{13}$ or SCIP ${ }^{14}$ ). The focus of our work is on SCIP and especially the SCIP Optimization Suite, with its MILP and MINLP solver SCIP and the LP solver SoPLex.
The branch-and-bound technique was first introduced by Land and Doig (1960). Similar to the concept of divide and conquer a problem is solved recursively by repeated divisions into subproblems. The high complexity of MILP solving stems from the fact that these subproblems are again MIPs-and often not significantly easier to solve-and that the tree that is generated in the process can grow exponentially large.
LP solutions provide a so-called dual bound that limits the possible primal bound, that is the value of an integer feasible solution, so entire subtrees can be safely excluded from the search. This pruning helps to keep the tree at a manageable size and also hints at the importance of good branching decisions, that is which variables define new bounds in the child nodes. There is an abundance of research items that are concerned with the design of branching rules: See Achterberg, Koch, and Martin, 2004; Achterberg and Berthold, 2009; Berthold and Salvagnin, 2013; Gamrath, Berthold, and Salvagnin, 2020 for details, especially regarding the branching rules of SCIP. The two main reasons for making MILP problems tractable in practice even for larger instances are powerful heuristics to find incumbent solutions and the clever exploitation of linear relaxations throughout the solving process. We refer to Berthold (2014) for a comprehensive analysis of primal heuristics.
Please note that the terms primal and dual appear both in the context of LP and MILP but they are not the same. For instance, there is no straightforward notion of a dual of an MILP. Instead, we typically only refer to primal and dual solutions with the latter one still being rooted in the primal space of variables ignoring the integrality restrictions. One can imagine the dual solution as the solution to the problem in an ideal or fantasy world that does not need to adhere to integrality rules and allows, for example, to send $1 / 3$ of a truck to half a warehouse. Consequently, interpreting the quality of the dual bound and the gap to the incumbent solution is strongly dependent on the chosen formulation to model the real-world problem. Often, there are multiple alternatives with various advantages and disadvantages and it is the task of an OR practitioner or model expert to choose a suitable one; this work is sometimes referred to as the "Art of Modeling".

In addition to that, the term duality also comes into play when computing presolving reduction to produce a more compact formulation. Here, dual reductions are based on the objective as opposed to primal reductions that are based on the feasible domain. For more information on duality of MILPs, we refer to Wolsey (1981).
Whenever we are speaking of a tree, we usually refer to the search tree that is generated by the branch-and-bound technique. In a similar manner, root-if not specified otherwise-refers to the first node, that is, the root of said tree and includes all further processing up until the first branching occurs.
To give this notion a more tangible representation we demonstrate what this tree

[^9]```
Algorithm 1.3 Concept of LP-based Branch-and-Bound for MILP

                if \(\chi_{\text {frac }}=\varnothing\) then
                            \(\hat{x} \leftarrow x^{\star} \quad / /\) found new incumbent solution
                        \(\hat{z} \leftarrow c^{\top} x^{\star} \quad\) // store new primal bound
                else
                        select \(x_{k} \in x_{\text {frac }} \quad / /\) choose branching candidate
                            \(L_{\Delta}=\left\{\mathrm{L} \mid x_{k} \geq\left\lceil x_{k}^{\star}\right\rceil\right\} \quad / /\) new lower bound for \(x_{k}\) in subproblem \(L_{\Delta}\)
                    \(\mathrm{L}_{\nabla}=\left\{\mathrm{L} \mid x_{k} \leq\left\lfloor x_{\mathrm{k}}^{\star}\right\rfloor\right\} \quad / /\) new upper bound for \(x_{k}\) in subproblem \(\mathrm{L}_{\nabla}\)
                    \(L_{\text {open }} \leftarrow \mathrm{L}_{\text {open }} \backslash\{\mathrm{L}\} \quad / /\) remove L from open problems
                    \(\mathrm{L}_{\text {open }} \leftarrow \mathrm{L}_{\text {open }} \cup\left\{\mathrm{L}_{\Delta}, \mathrm{L}_{\nabla}\right\} \quad / /\) add new child nodes to open problems
                end if
                end if
        end if
    end while
    if \(\hat{z}<\infty\) then
        Return: optimal solution \(\hat{\chi}\) with solution value \(\hat{z}\)
    else
        Return: MILP (1.1) is infeasible
    end if
```

looks like in various stages of the solving process in Figure 1.4. We can see how cutting planes, bound propagation, and conflict graphs can already improve the quality of the root relaxation by pushing the dual bound upwards. We explain the details of the used visualization tool TreeD (Miltenberger, 2021b) in Section 4.8.

### 1.4.1. SCIP Optimization Suite

The SCIP Optimization Suite is a one-of-a-kind software project that has been used by several generations of bachelor, master, and PhD students for their research. It is also used by commercial software vendors to enable fast and reliable linear and integer optimization applications. The SCIP Optimization Suite in version 7 comprises several partly independent software packages and tools:

SCIP The constraint integer solving framework is the heart of the SCIP Optimization Suite and ties all other packages together. SCIP provides code to handle a large range of problem classes from LP over MILP to (mixed-integer) non-linear optimization. It is written in C and started as PhD project of Achterberg (2009). SCIP has a modular plug-in structure that allows for straightforward code extensions.

SoPLex The C++ implementation of the simplex method is the oldest component of the project and provides LP solving capabilities to SCIP. We describe SoPlex in more detail in Chapter 3 as it plays a major role in this thesis.

ZIMPL The Zuse Institute Mathematical Programming Language was developed by Koch (2004a) to provide an open-source modeling tool to efficiently formulate various kinds of optimization problems in an intuitive syntax.

GCG The Generic Column Generation framework extends SCIP to provide support for solving extremely large instances that do not require to handle all variables upfront but generates them during the solving process. This branch-and-price project was started by Gamrath and Lübbecke (2010).

UG The Ubiquity Generator is another extension that facilitates running SCIP (and other software that generate some kind of tree) on massively parallel hardware. Shinano et al. (2012) describe the approach that has been successfully used to find optimal solutions to several problem instances for the very first time.

There are several aspects that make SCIP unique: Firstly, and often taken for granted, is the high-quality code with lots of documentation and several extensive release reports that meticulously describe new features and improvements. The SCIP Optimization Suite supports a wide range of APIs and is continuously tested for stability and correctness. There is an active community all around the world engaging with the software and its developers and also contributing to the project. The SCIP Optimization Suite is actively developed at different research institutes and universities and used for teaching in Operations Research and Discrete Mathematics. Numerous previous developers are now working on commercial solvers like CPLEX, Gurobi, and Xpress

(a) Root node processing
(b) Tree search

(c) Finished optimization

Figure 1.4.: Visualization of the MILP solving process using Treed and SCIP 7.0 of MIPLIB3 instance lseu. In Figure 1.4a, the dual bound (green line) is at root node level before the first branching. Figure 1.4 b shows the primal and dual bounds moving towards each other while in Figure 1.4c, SCIP already found the optimal solution and no open nodes are left. Note that the optimum is only known at the final stage and has been added to the previous pictures for a better understanding. The same applies for the already present tree paths. The color of the individual nodes shows the age of those nodes, that is, the order in which they are processed.
while still keeping in touch with the SCIP community. It is also rare that an academic software project is developed, maintained, and extended over several decades-and to date, SCIP shows no sign of slowing down in the future.

### 1.4.2. Other Solvers

In the world of commercial integer optimization, there are the three dominant solvers CPLEX (IBM, 2021), GUROBI (Gurobi Optimization, LLC, 2021), and XPRESS (FICO, 2021). All of them have a mature code base with Gurobi being the youngest. Most notably, CPLEX has been very popular with academic research projects and to date is probably the most prevalent also in the commercial sector-although there are barely any reliable numbers about this. These solvers exhibit state-of-the-art performance and stability and have been competing for the title of "fastest solver" for many years. Although they provide solving capabilities beyond LP and MILP, we will not discuss this here. Instead, we focus on their performance impact as LP solvers inside SCIP in Chapter 4.
There are also smaller commercial solver vendors like MOSEK (MOSEK ApS, 2016) that specialize in certain problem classes or solving techniques. MOSEK is also included in some of our experiments with SCIP.
In regards to academic or open-source MILP solvers, we want to mention CbC (Forrest, Vigerske, Santos, et al., 2020), supported by the COIN-OR Foundation ${ }^{15}$. Per-formance-wise, this solver is lagging behind SCIP and often cannot handle larger or harder models. The LP solver CLP (Forrest, Vigerske, Ralphs, et al., 2020) that is used in CBC, though, has a quite impressive performance and often beats SoPLEX. Other wellknown open source solvers are GLPK ${ }^{16}$ and LPSOLVE ${ }^{17}$. Despite their nominal emphasis on linear programming, they can actually deal with integer problems as well. They are still used fairly wide-spread due to their accessibility but they fall behind in terms of performance and, unfortunately, development efforts for most of these codes appear to have slowed down in recent years.

A relatively new solver is HiGHS ${ }^{18}$, headed by Dr. Julian Hall. HiGHS can handle both LPs and MILPs and already surpasses CLP and CBC in terms of performance and stability. Huangfu and Hall (2018) describe the main features of the solver, most notably the parallel simplex implementation. We did not include HiGHS as an LP solver for SCIP in our experiments in Chapter 4 because the corresponding interface is not yet stable and reliable enough. We are confident that HiGHS will play a major role in the academic and open-source linear and integer optimization community in the years to come.

[^10]
### 1.5. Testing Methodology

This work contains several computational experiments to test and verify the different implementations and algorithmic ideas. To facilitate fair and unbiased comparisons we run the experiments on identical hardware and, if necessary, use aggregated results using different random seeds to limit white noise influence and performance variability. Every job is executed exclusively on a single machine to avoid any sideeffects that usually occur when running multiple optimizations in parallel. The runs were conducted on a cluster with Inte ${ }^{\circledR}$ Xeon ${ }^{\circledR}$ Gold 5122 processors running with a clock speed of 3.6 GHz and 96 GB of memory.
We use the evaluation tool IPET (Hendel, 2021) and various common Python plotting libraries like matplotlib, seaborn, and plotly. Unless mentioned otherwise, we use the MIPLIB 2017 benchmark set (Gleixner, Hendel, et al., 2021) as the foundation for MILPbased experiments. For most LP-based experiments, we use a modified SCIP version that reads all input files as linear programming problems, effectively ignoring any integer restrictions. This allows for LP solver comparisons in a controlled environment with identical error checks and a unified output.

Our LP instance set consists of a culmination of several widely used and popular test sets from the LP and MILP communities:

- Netlib LP test set ${ }^{19}$
- Csaba Mészáros's LP collection ${ }^{20}$
- COR@L ${ }^{21}$
- MIPLIB (Bixby, Boyd, and Indovina, 1992), MIPLIB 3 (Bixby, Ceria, et al., 1998), MIPLIB 2003 (Achterberg, Koch, and Martin, 2006), MIPLIB 2010 (Koch, Achterberg, et al., 2011), and MIPLIB 2017 (Gleixner, Hendel, et al., 2021)

The shifted geometric mean has been established as the standard measure for comparing performance across a set of instances. It is defined for a set of data points $\mathrm{t}_{1}, \ldots, \mathrm{t}_{\mathrm{k}}$ as

$$
\left(\prod_{i=1}^{k}\left(t_{i}+s\right)\right)^{1 / k}-s
$$

These data points are typically solving times or node counts of the MILP solver. The corresponding shift value has to be chosen accordingly and serves to dampen the effects of large relative differences in small numbers of $t$. We will note the shift values for the single experiments whenever it is not 1 second for time measurements or 100 for node counts.

[^11]

Figure 1.6.: Number of iterations and time to optimality (using a time limit of one hour) with respect to the number of non-zero elements in the problem matrices

## Chapter 2

## PySCIPOPT

High-performance optimization solvers rely on an implementation that is close to the machine, so all state-of-the-art codes-from commercial to free and open-source-are written in a programming language that is considered low-level by today's standards. The most popular programming languages for this area are $\mathrm{C} / \mathrm{C}++$.
$C / C++$ enable the creation of very efficient solvers that can put the available hardware resources to best use. This comes at the cost of a significantly higher development cost, that is, a longer time from idea to prototype to production code than in other higher-level programming languages. Python ${ }^{1}$, on the other hand, is one of the languages that tries to minimize this development cost at the price of an often notably worse performance when executing the code.

Bjarne Stroustrup, the author and designer of the C++ language once said: "There are only two kinds of programming languages: those people always complain about, and those nobody uses" ${ }^{\prime 2}$ - concisely making the point that there will always be certain trade-offs in programming.

For prototyping new algorithmic concepts and for less performance-critical features, Python is very well suited. One of its main charms is that Python is an interpreted language and can be executed without a dedicated compilation step: Users can write new code and immediately run it.

Using clever language extensions like Cython ${ }^{3}$ (Dalcin et al., 2011), we are able to combine the best features of both programming language aspirations: PYSCIPOPT (Maher, Miltenberger, et al., 2016) leverages Python's fast prototyping while relying on SCIP's C engine to avoid sacrificing too much performance. Coincidentally, Cython or more precisely its predecessor Pyrex, is just as old as SCIP, celebrating its $20^{\text {th }}$ anniversary in $2022^{4}$.

[^12]
### 2.1. Concept

We were inspired by the popular and highly regarded design of Gurobi's Python interface when creating the concept for PySCIPOPT. Furthermore, Prof. João Pedro Pedroso ${ }^{5}$ encouraged this decision with his intent to publish a text book about mathematical optimization with PYSCIPOPT ${ }^{6}$ as a translation of the Japanese edition by Kubo et al. (2012) that is built around Gurobi.

The core concept of PYSCIPOPT consists of two components-modeling and feature development-that we want to explain in the following paragraphs.

### 2.1.1. Modeling

When designing a tool for the creation of mathematical optimization models, one important aspect is to have a close connection between the computer code and the mathematical formulation. Ideally, one should be able to comprehend the meaning of the individual sets of variables and constraints just as easy from reading the code as from reading the mathematical formulation. To achieve this goal in PYSCIPOPT, we use operator overloading and intuitive object-oriented classes to represent the entities of a model instance, like variables, constraints, and operators. The following example taken from Maher, Miltenberger, et al. (2016) illustrates this:
from pyscipopt import Model

```
m = Model()
x = m.addVar("x")
y = m.addVar("y", vtype="I")
m.setObjective(x + 3*y)
m.addCons(2*x - y*y >= 10)
```

$$
\begin{array}{rlrl}
\operatorname{minimize} & x+3 y & \\
\text { subject to } & 2 x-y^{2} & \geq 10 \\
x, y & \geq 0 \\
x & \in \mathbb{R} \\
y & \in \mathbb{Z}
\end{array}
$$

We also see from this example that sensible default values are used to fill in method parameters that are not set explicitly by the user. This allows the code to stay minimal and readable while still providing all the advanced functionality from the underlying SCIP methods. Additionally, Python also allows passing these parameters in any order as long as the name of the parameter is specified. For completeness, this is the full specification of the addVar() method:

[^13]```
def
    addVar(
```

    self, \# the PySCIPOpt model
    name="", \# variable name
    vtype="C", \# variable type ("C", "B", or "I")
    lb=0.0, \# lower bound
    ub=None, \# upper bound
    obj=0.0, \# objective coefficient
    pricedVar=False) \# whether this is a pricing candidate
    This paradigm of staying close to SCIP while offering more convenience is consistent throughout the package to appeal to newcomers and SCIP experts alike.

### 2.1.2. Feature Development

Employing PySCIPOPT purely as a framework to formulate and solve a model instance programmatically and then querying the resulting solution values is a common use case. However, many users would like to extend the available feature set in SCIP with their own algorithmic ideas. To make this possible, we support the majority of SCIP's comprehensive API to allow fine-grained control of how the solver handles a certain model instance.
SCIP's modular structure provides callback functions for almost every component of the branch-and-cut-and-price solving process. These callbacks can be implemented in pure Python code and are then called through PySCIPOPT during runtime of the solver. There is no compilation step necessary to make changes in the Python code, which facilitates rapid prototyping.
The most popular callbacks include custom cutting plane separation techniques, primal heuristics, and also constraint handlers that provide everything necessary to define entirely new user-specific constraint types.

### 2.2. Technical Details

The methods implemented in PYSCIPOPT can loosely be categorized into three groups:
convenience functions These are functions that have no direct counterpart in SCIP but make feature development and model building more intuitive and straightforward. A good example is the addCons( ) method. It encapsulates multiple SCIP functions to add linear, quadratic, and general nonlinear constraints in a single function call. Convenience functions hide some of SCIP's complexity and make PYSCIPOPT more appealing and user-friendly.

SCIP wrappers These are relatively straightforward wrappers of SCIP functions that often do not consist of more than two or three lines of code and just replicate

| repetitions | number of variables n | PYSCIPOPT | SCIP |
| ---: | ---: | ---: | ---: |
| 5 | 1000 | 0.09 sec | 0.03 sec |
| 5 | 10000 | 0.65 sec | 0.09 sec |
| 5 | 100000 | 6.34 sec | 0.72 sec |
| 5 | 1000000 | 64.41 sec | 8.48 sec |

Table 2.1.: Performance comparison of building model 2.1 in PySCIPOPT using Python and in SCIP using C
a certain SCIP functionality. Wrapper functions account for the majority of functions implemented in PySCIPOPT and can be used whenever there are no complex data structures involved in the specific call, for example when changing the bounds of a variable.
internal helper functions These are needed to organize the code better, to provide improved structure, and to outsource some frequently needed functionality that should be hidden from the user.

The individual plug-in types are implemented in an object-oriented fashion. Every new user plug-in needs to be extended from the given base class, that provides the function stubs. Some of these functions are mandatory for a working implementation and some are optional.

To give an example: the heuristics plug-in needs to implement the heurexec () function to tell SCIP what this custom heuristic is supposed to do. It is not necessary, though, to also implement heurinit ( ) if no additional initialization step is required to run the heuristic.

We refer the interested reader to the many different examples and test cases available in PYSCIPOPT that demonstrate typical use cases and should provide a good starting point for further code development.

### 2.3. Performance

We compare the performance of building a simple LP model like this:

```
min}\mp@subsup{1}{1}{\top}
s.t. }\mp@subsup{x}{i}{}+\mp@subsup{x}{i+1}{}\geq1\quad\foralli\in{1,\ldots,n
        x}\geq0
```

This model is built five times for different values of $n$ to get a reliable performance measure. As we can see from Table 2.1, building a model from formulation 2.1 takes about eight times longer with PYSCIPOPT than using SCIP's C API directly.

While this undoubtedly is a significant disadvantage for PYSCIPOPT, the amount of code required to formulate this model in the two programming languages also differs dramatically:

## PYSCIPOPT:

```
def buildmodel(nvars):
    m = Model("bench")
    x = {}
    for i in range(nvars):
            x[i] = m.addVar(name=f"x_{i}", obj=1)
    for i in range(nvars - 1):
            m.addCons(x[i] + x[i + 1] >= 1, name=f"c_{i}")
```

## C API of SCIP:

```
static
SCIP_RETCODE buildmodel(int nvars)
{
    char name[SCIP_MAXSTRLEN];
    SCIP* scip;
    SCIP_VAR** x;
    SCIP_CONS* c;
    int i;
    SCIP_CALL(SCIPcreate(&scip));
    SCIP_CALL(SCIPincludeDefaultPlugins(scip));
    SCIP_CALL(SCIPcreateProbBasic(scip, "bench"));
    SCIP_CALL(SCIPallocMemoryArray(scip, &x, nvars));
    for(i = 0; i < nvars; ++i)
    {
        (void) SCIPsnprintf(name, SCIP_MAXSTRLEN, "x_%d", i);
        SCIP_CALL(SCIPcreateVarBasic(scip, &x[i], name, \odot,
            SCIPinfinity(scip), 1.0, SCIP_VARTYPE_CONTINUOUS));
        SCIP_CALL(SCIPaddVar(scip, x[i]));
    }
    for(i = 0; i < nvars-1; ++i)
    {
        (void) SCIPsnprintf(name, SCIP_MAXSTRLEN, "c_%d", i, i);
        SCIP_CALL(SCIPcreateConsBasicLinear(scip, &c, name, \odot,
            NULL, NULL, 1, SCIPinfinity(scip)));
        SCIP_CALL(SCIPaddCoefLinear(scip, c, x[i], 1.0));
```

```
        SCIP_CALL(SCIPaddCoefLinear(scip, c, x[i+1], 1.0));
        SCIP_CALL(SCIPaddCons(scip, c));
        SCIP_CALL(SCIPreleaseCons(scip, &c));
    }
    for(i = 0; i < nvars; ++i)
        SCIP_CALL(SCIPreleaseVar(scip, &x[i]));
    SCIPfreeMemoryArray(scip, &x);
    SCIP_CALL(SCIPfree(&scip));
    return SCIP_OKAY;
}
```

After the model is created and the optimize call is executed, both approaches will perform the actual optimization in the same time because PYSCIPOPT is then just calling SCIP's solving routines without any further detours.

PySCIPOPT is not the only software package with the aim to make mathematical programming more accessible but, to date, it is arguably the best solution to work with the deeper data structures and algorithmic components of SCIP without requiring $\mathrm{C} / \mathrm{C}++$ proficiency. For plain modeling or basic callback interfaces from Python, we would also like to mention the frameworks Pyomo (Hart, Watson, and Woodruff, 2011; Bynum et al., 2021) and PuLP7. These tools enable the user to run different commercial and academic or open-source LP, MILP, or general solvers with the same Python code to formulate the models. Because of this flexibility, they lack the functionality and deeper integration of PYSCIPOPT and other custom-built or proprietary tools.

JUMP (Dunning, Huchette, and Lubin, 2017) is a software package for the programming language Julia (Bezanson et al., 2017) and has potential to rival PYSCIPOPT and other Python-based tools in its usability and performance. Until now, Julia is still a niche programming language that does not yet have a large community and ecosystem of libraries compared to other languages.

### 2.4. Licensing and Impact

PySCIPOPT is licensed under the permissive free software MIT license making it easy for contributors to extend the feature set or provide bug fixes or other code improvements. There are automatic builds and a large test suite configured to verify every single commit that is pushed to the public GitHub repository. This Continuous Integration approach allows for better maintainability and consistent code quality. There is a growing number of researchers that prefer using PYSCIPOPT for their work to avoid technical complications with C/C++. PYSCIPOPT is also increasingly popular with academic lectures and courses teaching applied mathematical programming. A famous

[^14]example is the ecole ${ }^{8}$ framework for combining machine learning with combinatorial optimization.
It is safe to say that PySCIPOPt has become the main entry point for users of the SCIP Optimization Suite with more than 500 stars on GitHub, 200 repository forks, and multiple dependent projects and packages as of October 2022.

[^15]
## Chapter 3

## Implementational Aspects of the Simplex Algorithm

The original publication of SoPLex by Wunderling (1996) is written in German and therefore inaccessible for large parts of the world of operations research. We want to remedy this by providing a description of the algorithm and explaining its advantages and unique features compared to other implementations.
SoPLex uses the revised primal and dual simplex algorithm to solve linear optimization problems. It is implemented in $\mathrm{C}^{++}$and a core component of the SCIP Optimization Suite. SoPlex embraces object-oriented programming leading to a modular structure of the different algorithmic components, like presolving, pricing, or scaling. A variety of presolving techniques help to reduce the problem size and speed up the solving process.
The name SoPLex is an abbreviation for sequential object-oriented simplex, with its two parallel variants DoPLex and SMoPLEx, referring to distributed and shared memory implementations respectively. While those parallel versions did show performance improvements in the original work of Wunderling (1996), they have never been made publicly available.

Until early 2018, SoPLex was used in the SPEC benchmark suite for CPU intensive codes SPEC CPU2006¹.

### 3.1. Stable Summation

There are ways to achieve summation results with double precision arithmetic that have smaller errors than a straightforward implementation (see Rump (2005) for further reference). This can be especially useful for summations of many values and for summations that are prone to numerical cancellation. Elimination happens when subtracting values of almost equal size. In this case most of the significant digits of both numbers vanish, leaving mainly numerical noise as the result.

[^16]We identified several places in both SCIP and SoPLex that might result in inaccurate summation results and applied a more sophisticated approach to compute the sum. For SoPlex this is done in all scalar products of any type of vector as well as in the different summations necessary for solving linear systems of equations using the LU factorization of the basis matrix.
The method splits the summation values into two double precision numbers and performs basis arithmetic on those pairs of high and low nominal values. While such methods can replace all basic arithmetic operations (sum, difference, product, and quotient), they are most important for summation due to its inherent numerical instability. There is a negligible performance impact compared to the usual computation because the additional internal additions can be performed efficiently, that is, in parallel, on modern CPUs.

It is difficult to assess the benefit of such a feature because in most cases those tiny numerical inaccuracies do not impede the computation of a correct solution within the usual tolerances. Still, we do see a positive effect of the stable summation when analyzing SCIP's performance solving MILPs as shown in Table 4.2. Note that although SCIP itself also implements the stable sum technique in various places, we only consider the performance impact of this feature within SoPlex.

### 3.2. Row Representation

The feature that makes SoPlex stand out from most other simplex implementations is its two-fold basis representation. While typical solvers-as well as the majority of textbooks-define the basis to be a subset of columns, one can also use a subset of rows. This can be seen as dualizing the perspective. There are several advantages of working with a so-called row basis, like easier addition and removal of rows, or a reduced basis size for certain problems.

Before we go into detail regarding the consequences, let us first formally define the row basis using this extended version of a linear programming problem:

$$
\begin{array}{ll}
\min & c^{\top} x \\
\text { s.t. } & {\left[\begin{array}{c}
\mathrm{L} \\
l
\end{array}\right] \leq\left[\begin{array}{c}
A x \\
x
\end{array}\right] \leq\left[\begin{array}{c}
u \\
u
\end{array}\right]}  \tag{3.1}\\
A \in \mathbb{R}^{m, n}, \quad c, l, u \in \mathbb{R}^{n}, \quad \mathrm{~L}, \mathrm{U} \in \mathbb{R}^{\mathrm{m}}
\end{array}
$$

Effectively, we remove the variable bounds and extend the constraint matrix from $A$ to $\left[\begin{array}{ll}A^{\top} & I\end{array}\right]^{\top}$.
The dual of (3.1) reads

$$
\begin{array}{rrrrr}
\text { max } & l^{\top} \mathrm{d}^{+} & -\mathrm{u}^{\top} \mathrm{d}^{-} & +\mathrm{L}^{\top} \mathrm{y}^{+} & -\mathrm{U}^{\top} \mathrm{y}^{-} \\
\text {s.t. } & \mathrm{d}^{+} & -\mathrm{d}^{-} & +\mathrm{A}^{\top} \mathrm{y}^{+} & -\mathrm{A}^{\top} \mathrm{y}^{-}=\mathrm{c}  \tag{3.2}\\
& \mathrm{~d}^{+}, & \mathrm{d}^{-}, & \mathrm{y}^{+}, & \mathrm{y}^{-} \geq 0 .
\end{array}
$$

The value $d_{j}=d_{j}^{+}-d_{j}^{-}$is commonly called the reduced cost of variable $x_{j}$. Note that these values are uniquely determined by the dual solution $y=y^{+}-y^{-}$.

Usually, bounds can also take values $\infty$ or $-\infty$, for ease of notation we are assuming them to be finite.

Definition 1 (basis, basic solution). Given a linear programming problem in form (3.1). Let $\mathcal{C} \subseteq\{1, \ldots, n\}$ and $\mathcal{R} \subseteq\{1, \ldots, m\}$ be index sets of variables and constraints of (3.1), respectively.

1. We call $\mathcal{B}:=(\mathcal{C}, \mathcal{R})$ a basis of (3.1) if $|\mathcal{C}|+|\mathcal{R}|=m$. Variables and constraints with index in $\overline{\mathcal{C}}:=\{1, \ldots, n\} \backslash \mathcal{C}$ and $\overline{\mathcal{R}}:=\{1, \ldots, m\} \backslash \mathcal{R}$, respectively, are called non-basic.
2. We call a basis $(\mathcal{C}, \mathcal{R})$ regular if the vectors $\mathcal{A}_{\mathrm{j}}, \mathfrak{j} \in \mathcal{C}$, and $e_{i}, i \in \mathcal{R}$, are linearly independent.
3. We call a primal-dual pair $(x, y) \in \mathbb{R}^{n} \times \mathbb{R}^{m} a$ basic solution of (3.1) if there exists a regular basis $(\mathcal{C}, \mathcal{R})$ such that

$$
\begin{align*}
x_{j}=l_{j} \text { or } x_{j} & =u_{j}, & & j \notin \mathcal{C} \\
A_{i} \cdot x=L_{i} \text { or } A_{i \cdot} \cdot x & =u_{i}, & & i \notin \mathcal{R} \\
y^{\top} A_{\cdot j} & =c_{j}^{\top}, & & j \in \mathcal{C}  \tag{3.3}\\
y_{i} & =0, & & i \in \mathcal{R}
\end{align*}
$$

4. A solution $(x, y)$ is called primal feasible if $\mathrm{L} \leq \mathrm{Ax} \leq \mathrm{U}, \mathrm{l} \leq \mathrm{x} \leq \mathrm{u}$. It is called dual feasible if

$$
\begin{equation*}
y_{i}=0 \vee\left(y_{i} \geq 0 \wedge A_{i} \cdot x=L_{i}\right) \vee\left(y_{i} \leq 0 \wedge A_{i} \cdot x=u_{i}\right) \quad \forall i \in\{1, \ldots, m\} \tag{3.4}
\end{equation*}
$$

and with $\mathrm{d}_{\mathrm{j}}=\mathrm{c}_{\mathrm{j}}-\mathrm{y}^{\top} \mathrm{A}_{\mathrm{j}}$

$$
\begin{equation*}
d_{j}=0 \vee\left(d_{j} \geq 0 \wedge x_{j}=l_{j}\right) \vee\left(d_{j} \leq 0 \wedge x_{j}=u_{j}\right) \quad \forall j \in\{1, \ldots, n\} \tag{3.5}
\end{equation*}
$$

holds.
$\mathcal{B}$ is the well known definition of a basis and in our work is referred to as the column basis.
Let us now define the row basis.
Definition 2 (row basis). The row basis $\mathcal{N}=(\overline{\mathcal{C}}, \overline{\mathcal{R}})$ is an $n$-dimensional subset of the (extended) rows of this LP.

As we can see, the general concept of partitioning variable and constraint indices into the four sets $\mathcal{C}, \mathcal{R}, \overline{\mathcal{C}}$, and $\overline{\mathcal{R}}$ allows us to define both a column basis $\mathcal{B}$ and a row basis $\mathcal{N}$. In Definition 1 we require the basis matrix $B$, corresponding to the column basis $\mathcal{B}$, to be regular. This is necessary for properly defining e.g., the solution values $x_{\mathcal{C}}$ that are not on their bounds, as we will see later. It is not immediately apparent that this regularity also holds for the row basis matrix N .

Lemma 3. Let $\mathcal{B}=(\mathcal{C}, \mathcal{R})$ be a basis of (3.1) according to Definition 1. The vectors $A_{. j}, j \in$ $\mathcal{C}$ and $e_{i} \in \mathbb{R}^{m}, i \in \mathcal{R}$ are linearly independent if and only if the (row) vectors $A_{i .}, i \in \overline{\mathcal{R}}$ and $e_{j}^{\top} \in \mathbb{R}^{n}, j \in \overline{\mathcal{C}}$ are linearly independent.

Proof. Partition constraint matrix $A$ according to basis $(\mathcal{C}, \mathcal{R})$ :

$$
A=\left[\begin{array}{ll}
A_{\mathcal{R} C} & A_{\mathcal{R} \bar{C}} \\
A_{\overline{\mathcal{R}} C} & A_{\overline{\mathcal{R}} \bar{C}}
\end{array}\right]
$$

This leads to the following partitioning of the basis matrices $B$ and $N$ :

$$
\mathrm{B}=\left[\begin{array}{cc}
A_{\mathcal{R} \mathcal{C}} & \mathrm{I}_{\mathcal{R}} \\
A_{\overline{\mathcal{R}} \mathcal{C}} & 0
\end{array}\right] \quad \mathrm{N}=\left[\begin{array}{cc}
0 & \mathrm{I}_{\overline{\mathcal{C}}} \\
A_{\overline{\mathcal{R}} \mathcal{C}} & A_{\overline{\mathcal{R}} \bar{C}}
\end{array}\right]
$$

For their determinants the following holds.

$$
\operatorname{det}(B)=-\operatorname{det}\left(A_{\overline{\mathcal{R}} \mathcal{C}}\right) \cdot \operatorname{det}\left(\mathrm{I}_{\mathcal{R}}\right)=-\operatorname{det}\left(A_{\overline{\mathcal{R}} \mathcal{C}}\right) \cdot \operatorname{det}\left(\mathrm{I}_{\overline{\mathcal{C}}}\right)=\operatorname{det}(\mathrm{N}) .
$$

Here, we are using the fact that the determinant of a block-triangular matrix is equal to the product of the determinants of the blocks on the diagonal:

$$
\operatorname{det}\left(\left[\begin{array}{cc}
A & B \\
0 & C
\end{array}\right]\right)=\operatorname{det}(A) \cdot \operatorname{det}(C)
$$

Furthermore, the two block matrices B and N can be transformed into the above blocktriangular form by multiplication of a (block-) permutation matrix with determinant -1 that exchanges the two block rows.

Corollary 1. Forming the inverse matrices of the basis matrices B and N shows that both rely only on the inversion of sub-matrix $A_{\overline{\mathcal{R}} C}$ :

$$
\begin{aligned}
& \mathrm{B}=\left[\begin{array}{cc}
A_{\mathcal{R C}} & \mathrm{I}_{\mathcal{R}} \\
A_{\overline{\mathcal{R}}} & 0
\end{array}\right] \\
& \mathrm{N}=\left[\begin{array}{cc}
0 & \mathrm{I}_{\overline{\mathcal{C}}} \\
A_{\overline{\mathcal{R}} \mathcal{C}} & A_{\overline{\mathcal{R}} \bar{C}}
\end{array}\right] \\
& B^{-1}=\left[\begin{array}{cc}
0 & A_{\mathcal{R} \mathcal{C}}^{-1} \\
\mathrm{I}_{\mathcal{R}} & -A_{\mathcal{R C}} \mathcal{A}_{\hat{\mathcal{R}} \mathcal{C}}^{-1}
\end{array}\right] \\
& \mathrm{N}^{-1}=\left[\begin{array}{cc}
-A_{\overline{\mathcal{R}} \mathcal{C}}^{-1} A_{\overline{\mathcal{R}} \overline{\mathcal{C}}} & A_{\overline{\mathcal{R}} \mathcal{C}}^{-1} \\
\mathrm{I}_{\overline{\mathcal{C}}} & 0
\end{array}\right]
\end{aligned}
$$

From Corollary 1 we see that it is possible to compute the inverse matrix of one representation using only the inverse of the other representation and some matrixvector products. We can transform data between representations as is required e.g., when using the row basis internally but need to communicate results in column representation, as is done in tableau-based cut generation.
The potential of this connection has already been explored by Gleixner (2012), where it is demonstrated that the inversion of $A_{\overline{\mathcal{R}}}$ is enough to formulate the entire simplex method in both primal and dual form. This technique has been called kernel simplex by Wunderling (2012) and is available for the dual simplex algorithm in CPLEX. From
personal communications with the author it seems that the proposed symmetrical simplex algorithm unifying primal and dual methods could not outperform the existing code base in CPLEX. We are not aware of any competitive implementation of this idea.

Note that the term kernel has also been used by various authors in the linear programming community, see e.g., Maros, 2003; Luce et al., 2009, to describe the nontrivial block during the LU factorization after performing some permutations.
The row representation seems not very intuitive when one is already familiar with the classical approach. On second thought, though, it can help to understand or visualize the concept of a simplex basis in the first place:

The intersection of all basic rows, be it a proper problem constraint or just a variable bound, defines the current vertex that corresponds to this basis. The connection to active set methods may also become more obvious as the row basis is precisely the active set in the simplex algorithm, as opposed to the set of non-basic variables in the traditional column representation.
Essentially, basic rows are tight, whereas the activity of a non-basic row is determined by the basic ones. This is the direct opposite of the definition of the column basis and explains the above notion of duality between the two representations.

From an algorithmic point of view, the primal simplex in column representation can be seen as an entering simplex since the arguably most significant part is selecting an entering index in the pricing step to improve the reduced costs. Equivalently, for the dual simplex in the same representation, we are searching for a leaving candidate in the pricing step to become primal feasible. Using a row basis, this notion of entering/leaving and primal/dual is interchanged and Table 3.1 captures this duality in the two representations quite nicely:

|  | column representation |  | row representation |
| :---: | :---: | :---: | :---: |
| entering type <br> leaving type | primal simplex <br> dual simplex |  | dual simplex <br> primal simplex |

Table 3.1.: Overview of the different basis representations and simplex variants.
Let us now discuss conceptional and especially computational advantages of the two representations.

### 3.2.1. Addition of Cutting Planes

When we add valid inequalities to an existing LP and a corresponding optimal basis, we lose primal feasibility but retain dual feasibility. The following re-optimization with the dual simplex can then be started at the previous basis and usually takes few iterations. As we also modify the dimensions of the problem, the basis size will increase when using the column representation making it necessary to compute a
new LU factorization or adapt the existing one-SoPLEx recomputes the factorization in most cases.

In the row representation, though, this is not necessary as the basis size is not linked to the number of constraints in the problem, so the factorization remains valid. Multiple new valid inequalities can be added to the set of LP rows without invalidating the factorization. This provides a computational advantage for problems that rely on a cut-focused solution approach.

See Section 4.5 for more details on the concept of cutting planes for solving MILPs.

### 3.2.2. Column Generation

In the column generation approach as described for example by Desaulniers, Desrosiers, and Solomon (2006), new variables or columns are generated during the optimization process and re-optimizations based on the previous LP basis are required. Analogous to Section 3.2.1, the existing LU factorization can be reused when working with the column representation but not with the row representation. In the latter, the basis size depends on the number of variables and changes throughout the solving process. Hence, we can expect a computational advantage of using the conventional column representation of the simplex method for this type of approach.

### 3.2.3. Different Problem Dimensions

Following the arguments in the preceding paragraphs, it should come as no surprise that there are advantages and disadvantages between the two representations just by regarding the dimensions of the problem in question as we can also see in Figure 3.2. Whenever there are more rows than columns, the row representation should be used to be able to work with a smaller basis matrix and profit from less memory consumption and shorter data arrays in the factorization. SoPlex automatically switches to the row representation when there are more than 1.2 times as many rows than columns in the problem. This threshold is not set to 1.0 because of some additional overhead with operations like computing the solution of a linear system with the basis matrix that require a transformation to the standard column representation. Such operations happen frequently when running SoPLex within a MILP solver.
Figure 3.1 visualizes how the choice of representation affects the solving times for the allLP test set. We only compare instances that can be solved with both settings and choose the best solving time over all seeds. Every instance has a data point either in the upper or lower part of the image depending on whether the row or the column representation yields better performance.

We can observe a trend of the column representation dominating the results for instances with more columns than rows. On the other hand, the winning instances for the row representation are more evenly distributed across the horizontal axis.
We use the instance dimensions after applying presolve reductions. The color intensity is calculated in the same manner as the row-column ratio and represents how strongly the other representation is dominated:

Figure 3.1.: Minimum solving times for row and column representation depending on row to column ratio on the allLP test set.

$$
\frac{t_{\text {row }}-t_{\text {col }}}{\max \left(t_{\text {row }}, t_{\text {col }}\right)}
$$

Of the 489 instances, 229 were won by the row representation and 228 were won by the column representation. For the remaining instances both settings yield similar performances. Please note that we only considered instances where the slower setting took more than one second to solve. An interesting result from this comparison is that many instances are solved faster despite a technically disadvantageous basis representation. The more suited representation usually pays off, though, when dealing with longer-running problem instances.

It is important to note that both basis matrix representations carry the same amount of meaningful information-the remaining entries of the basis matrices are merely filled up with the corresponding parts of an identity matrix. This also means that despite the greater matrix dimensions, the amount of work required to factorize the matrix into LU form is not growing in the same ratio and can be carried out by simple permutations. Luce et al. (2009) showed that for most problems in practice, this is even true in general, that is, also for the smaller of the two variants. The so-called Markowitz pivoting technique (Markowitz, 1957) is used in most simplex implementations to perform the LU factorization and is able to handle these identity parts as

Figure 3.2.: Row ( N ) and column (B) basis matrix sizes for different problem dimensions $A_{1}$ and $A_{2}$
well. The main idea here is to construct a permutation that favors elements of maximal sparsity while preserving numerical stability-a row and column singleton with a 1 as only entry is always going to be preferred over any other rows and pushes all rows associated to the identity matrix to the front. We refer to the paper of Luce et al. (2009) for a comprehensive coverage of this part in the simplex algorithm.

### 3.3. Shifting to Generate a Feasible Basis

The primal and dual simplex algorithms require either a respectively primal or dual feasible starting basis. For a general LP instance it is unlikely that the typical starting basis consisting of all slack variables is feasible right away. In that case we need to perform some kind of transformation or solve an auxiliary problem to satisfy the necessary working conditions of the simplex algorithm. In a very recent paper, Huang et al. (2021) list several different simplex initialization variants and provide an overview as well as an outlook on the possibilities of using machine learning techniques to further improve upon the existing ideas. Their paper mainly discusses methods to create advanced starting bases that go beyond mere feasibility and also aim to achieve better numerical properties and a shorter iteration count to reach optimality. See also Galabova and Hall (2020) for a comprehensive description of one such method. One drawback of these initialization heuristics is that they are more expensive and do not provide a guarantee of leading to fewer iterations. Furthermore, the computation of accurate steepest edge weights is more time consuming compared to using the identity matrix as starting basis. Although SoPLex also implements code to compute an advanced starting basis, in our experience this did not result in improved overall performance.

Commonly, finding a feasible basis involves solving the so-called phase-1 problem. A rather straightforward way is the following: every constraint is extended by a new artificial variable rendering the trivial starting basis feasible so the primal simplex algorithm can be applied. Additionally, the objective function is modified to minimize
the value of these new artificial variables:

$$
\begin{align*}
& \min 1^{\top} z \\
& \text { s.t. } A x+z=b  \tag{3.6}\\
& x \geq 0 \\
& z \geq 0
\end{align*}
$$

We can use a primal feasible starting basis that sets all artificial variables $z$ to be basic and all structural variables $x$ onto their lower bounds. Optimizing this auxiliary LP should end up with a basis that is primal feasible for the original problem if and only if the objective function value is 0 , that is, all artificial variables $z$ are 0 .
In case where the optimal basis does have a positive objective function value, the original problem instance is infeasible: There is no variable setting for $x$ that satisfies all constraints without the help of adding $z$ variables.

SoPlex on the other hand performs a so-called shifting technique to set up a feasible starting basis for either the primal or dual simplex method. In the primal case we require a basis that satisfies all bound and side constraints. Instead of modifying the basis, we simply relax all those violated constraints until they are satisfied. The resulting modified LP will be primal feasible for the trivial slack basis that sets all structural variables to either of their bounds and consists of only row variables.
After the primal simplex has found an optimal solution, that is, an optimal basis is available, we can tighten the previously relaxed constraints again. While this operation is breaking primal feasibility it is not going to impact the dual feasibility of the basis, so the dual simplex method can be started from this basis to eliminate all primal violations.
In a similar fashion we can also relax dual violations and start the optimization process with the dual simplex method and clean up using the primal method.

### 3.4. Long Steps in the Dual Simplex

This section is about a modification of the ratio test in the dual simplex that allows for a reduction of iterations by essentially performing multiple iterations combined. We implemented this technique in SoPlex version 1.6 .0 and it has since become the default ratio test when using the dual simplex.

### 3.4.1. Mathematical Background

The idea of long steps in the dual simplex method has been known for a long time. It was introduced in a Russian article (Kirillova, Gabasov, and Kostyukova, 1979) and later translated into English by Kostina (2002) making it available to wider audience. Even before, the method is mentioned in an unpublished draft report by Fourer (1994). Maros (2003) and Koberstein (2005) give a detailed description of the procedure and explain how it can be implemented. Still, there are a few aspects of the method also
known as bound flipping ratio test that have not yet been mentioned in the literature. We need to sketch the algorithmic idea to be able to formulate them.

The bound flipping ratio test is only applicable in the dual simplex method and for problem instances that have variables or constraints with both upper and lower bounds. Its main idea is that dual feasibility can be maintained by switching or flipping the bound a non-basic variable is set to. This happens during the ratio test, that is, when determining the next non-basic index that needs to become basic to not violate feasibility. From Definition 1 we know that dual feasibility depends on the sign of the dual variable $y_{i}$ or $d_{j}$ in conjunction with the upper or lower bound being tight for the respective primal variable $x_{j}$ or constraint $A_{i .} x$. Hence, when the dual step length exceeds beyond the first break point, the corresponding dual variable changes its sign, rendering it infeasible for the current bound setting. Flipping the bound allows to further enlarge the step length. This can be repeated until no progress in the dual objective function is possible anymore.

### 3.4.2. Dual Pivot

In the following we want to explain the steps involved in a dual pivot, that is, a basis change that conserves dual feasibility and increases the dual objective function value while trying to reduce primal infeasibility. This example is done by using the column representation and follows the detailed description found in the PhD thesis of Koberstein (2005).

Beginning with a dual feasible basis $\mathcal{B}$ with $p \in \mathcal{B}$ being a violated primal variable, say $x_{p}>u_{p}$, that was chosen during the pricing step. This variable will be set to $u_{p}$ and therefore leaves the basis. The corresponding reduced cost value $d_{p}$ moves from 0 to some non-positive value. To compensate this change, also the dual variables $y$ need to be modified to preserve dual feasibility.
Summarizing, the dual pivot can be described by the change $t \in \mathbb{R}$ of the pth dual basic constraint $y^{\top} A_{. p}=y^{\top} B_{. p}$ :

$$
\begin{align*}
t & =y^{\top} B_{\cdot p}-\tilde{y}^{\top} B_{\cdot p}  \tag{3.7}\\
\tilde{y}(t)^{\top} & =y^{\top}-t \cdot e_{p}^{\top} B^{-1}  \tag{3.8}\\
\tilde{d_{\mathcal{N}}}(t)^{\top} & =d_{\mathcal{N}}^{\top}+t \cdot e_{p}^{\top} B^{-1} A_{\mathcal{N}}  \tag{3.9}\\
\tilde{Z}(t) & =Z+t \cdot\left(x_{p}-u_{p}\right) \tag{3.10}
\end{align*}
$$

Here, $Z$ represents the current dual objective value. For this example, we require $t \geq 0$ to ensure $\tilde{Z} \geq Z$ because we need to maximize the dual objective when solving LP 1.2 and $x_{p}>u_{p}$. The dual ratio test determines the correct size of $t$ and therefore also the non-basic index that should become basic. The final dual step length $t=\alpha_{D}$ (see also Algorithm 1.2) is computed according to (3.8) and (3.9) to satisfy $\tilde{y}_{q}=0$ or $\tilde{d}_{q}=0$ for one $q \in \mathcal{N}$.

In the conventional ratio test, the first entry $\mathrm{d}_{\mathrm{q}}, \mathrm{q} \in \mathcal{N}$ in the reduced cost vector to become 0 while enlarging the absolute value of $t$, will define the entering pivot index. As soon as the step length is increased further, dual feasibility will be violated.

The bound flipping ratio test, on the other hand, allows us to choose such a larger step length to improve the objective function value even further. Since the dual simplex algorithm needs to preserve dual feasibility, it is necessary to repair the introduced violations. This can be done by flipping the corresponding primal non-basic variables from their lower to their upper bound or vice versa according to the feasibility conditions (3.5) and (3.4). This technique can only work for variables or slacks that are (finitely) bounded from both sides, of course. Another point to consider is that with every performed bound flip the following objective function improvement step is decreased. It is important to keep track of this behavior and to stop enlarging the step length before the dual objective function value is reduced again and bound flips become detrimental.
From (3.10) we can see that the initial slope of $\tilde{Z}(t)$ is the primal violation of the leaving variable. This variable $x_{p}$ depends on the values of the non-basic variables. If, for instance $\chi_{q_{k}}, q_{k} \in \mathcal{N}$ is flipped from $l_{q_{k}}$ to $u_{q_{k}}$ the new value $\hat{x}_{p}$ of $x_{p}$ is computed as follows:

Therefore, the update formula for the dual objective function value needs to incorporate the new slope after the bound flip (note that we use $\dot{\chi}_{\text {p }}$ to denote a single step update):

$$
\begin{aligned}
\tilde{Z}(t) & =Z-t_{1}\left(x_{p}-u_{p}\right)-\left(t_{2}-t_{1}\right)\left(\dot{x}_{p}-u_{p}\right) \\
& =Z-t_{1}\left(x_{p}-u_{p}\right)-\left(t_{2}-t_{1}\right)\left(x_{p}+e_{p}^{\top} B^{-1} A \cdot q_{1}\left(u_{q_{1}}-\ell_{q_{1}}\right)-u_{p}\right)
\end{aligned}
$$

The dual objective function increase is a piecewise linear function as depicted in Figure 3.3. The number of bound flips that can be performed in one iteration depends on how quickly the slope flattens. In case there is a pivot candidate $x_{\mathfrak{q}_{k}}$ with an infinite bound the slope would be $-\infty$ and the procedure needs to be stopped.
After a number of bound flips have been performed and the entering index is chosen, it is necessary to update the basic solution as well to correspond to the changed non-basic values. This requires one additional solve with the basis matrix that can be done together with the mandatory FTRAN operation at the end of every simplex pivot. The change in the basic solution is determined by the difference between two flipped bounds:

$$
\left[\begin{array}{l}
\hat{x}_{\mathcal{C}} \\
\hat{s}_{\mathcal{R}}
\end{array}\right]=\left[\begin{array}{l}
x_{\mathcal{C}} \\
s_{\mathcal{R}}
\end{array}\right]+B^{-1}\left(\hat{s}_{\overline{\mathcal{R}}}-A_{\cdot \mathcal{C}} \hat{\mathcal{C}}_{\overline{\mathcal{C}}}\right)
$$

with

$$
\hat{s}_{\overline{\mathcal{R}}}=\sum_{i \in\left\{L_{i} \ngtr U_{i}\right\}}\left(U_{i}-L_{i}\right) e_{i}+\sum_{i \in\left\{U_{i} \rtimes L_{i}\right\}}\left(L_{i}-U_{i}\right) e_{i}
$$

Figure 3.3.: Development of the dual objective function value with bound flips: $t_{1}$ refers to the step length of the conventional ratio test, $Z_{2}$ and $Z_{3}$ are further improvements on the objective function, $\dot{\chi}_{p}$ and $\ddot{\chi}_{p}$ are new values for $x_{p}$ after the first and the second bound flip, respectively.
and

$$
\hat{x}_{\overline{\mathcal{R}}}=\sum_{j \in\left\{\mathfrak{l}_{j} \not u_{j}\right\}}\left(u_{j}-l_{j}\right) e_{j}+\sum_{j \in\left\{u_{j} \rtimes l_{j}\right\}}\left(l_{j}-u_{j}\right) e_{j} .
$$

### 3.4.3. Technical Improvements

We want to mention two technical improvements that can be implemented with the bound flipping ratio test and that to the best of our knowledge have not been described in the literature before.

Early Termination The textbook ratio test is usually performing two passes over the pivotal row. This is commonly known as Harris ratio test after Harris (1973) and tries to make a more stable pivot selection by allowing a small violation of feasibility. This violation can later be repaired by switching the simplex type from primal to dual or vice-versa. In the bound flipping ratio test the same approach can be applied while also storing the individual pivot candidates for subsequent sorting. We can save the best candidate during this collection phase and immediately return the selection in case no bound flips are possible. This avoids having to sort the candidates first and is a rather straightforward technique to avoid unnecessary operations.

Quick Selection When traversing the collected break points, we require them to be sorted in ascending order. This can be done by means of algorithms like quick-sort. In SoPLex, we use a partial quick-sort to avoid having to arrange the entire list beyond
the final flip that still improves the objective. The sorted part of the list is iteratively extended whenever more bound flips can be performed, providing at least the next $k$ smallest elements in every new call-in SoPlex, k is set to four. This ensures that all predecessors of the selected element can be processed accordingly and dual feasibility is maintained.

In fact, the order of the flipped candidates is irrelevant, as long as they are not larger than the selected one. For such a scenario an implementation of the weighted-median-selection algorithm can be applied. This method selects the maximal number of smallest elements-according to their weights-to not exceed a certain capacity. This capacity is represented by the dual objective improvement. As this precisely meets the requirements of the bound flipping ratio test, we can save some computational overhead by not having to sort the flipped candidates.
While appearing computationally inferior, we still use the partial quick-sort implementation in SoPLEx because a prototype version of the weighted-median-selection approach did not result in a positive performance impact.

### 3.4.4. Performance Impact

To demonstrate the effect of the bound flipping ratio test we compare the performance on the Netlib LP instance fit2d (see Table 3.2). This instance is well-suited for the bound flipping ratio test with its 10500 variables, all of which are boxed, that is, have lower and upper bounds. The problem instance is also very dense with just 25 constraints and exhibits a 10 -fold improvement in solving time and a 20 to 30 -fold reduction of iterations compared to the simpler ratio test without bound flips.

|  | steepest edge |  |  | devex |  |
| :--- | :---: | :---: | :--- | :--- | :---: |
|  | time | iterations |  | time | iterations |
| no bound flips | 0.8 | 6168 |  | 1.37 | 12841 |
| long step rule | 0.08 | 283 |  | 0.13 | 432 |

Table 3.2.: Performance impact of the bound flipping ratio test on Netlib instance fit2d with SoPLEX 5.0.2 and two different pricing variants.

Of course, we cannot evaluate the performance of any feature by inspecting just a single instance, so please refer to Table 3.4 for a more comprehensive LP performance impact analysis. We see an increased iteration count of $17 \%$ when disabling long steps and an increase of $7 \%$ with regards to the overall solving time. This benchmark compares the pure LP performance across the allLP instance set.

Still, we want to emphasize that this technique is very much dependent on the problem instance to be solved. We would also like to note that, keeping true to the objectoriented design of SoPLEx, the bound flipping ratio test is implemented as sub-class of the previous default method fast ratio test and is able to fall back easily if no bound flips are possible for a specific instance. Every $100^{\text {th }}$ iteration, another try with the
bound flipping ratio test is performed when otherwise no successful long steps could have been performed.

Finally, we need to add that despite our best efforts the bound flipping ratio test does not have a significant performance impact on SCIP when running the MIPLIB 2017 benchmark as shown in Table 4.2. There is a considerable reduction in the number of simplex iterations but this does not carry over to an improved overall solving time.

### 3.5. Pricing Variants

The pricing step in the simplex algorithm determines which edge of the polyhedron to cross in order to reach a neighboring vertex. Often, there are multiple options to go from one basis to an improving one. The choice of the pricing method can drastically impact the number of iterations, as it is defining this path to optimality.

There have been numerous studies about simplex pricing rules and the two most popular and successful methods have proven to be devex pricing and steepest edge pricing. The pricing rule chooses the next step direction based on the currently not fulfilled optimality conditions-dual infeasible variables in the primal simplex and primal infeasible variables in the dual simplex-a natural approach is to always take the most violated candidate. This pricing rule is known as Dantzig pricing, named after the simplex inventor George Dantzig, but just like the most infeasible branching rule in MILP solving it turns out to be a very impractical technique as shown by Achterberg, Koch, and Martin (2004). Its bad performance with respect to the total number of iterations is due to its lack of direction optimality. This is exactly where other pricing rules step in and try to improve upon by computing a weighted pricing score.

### 3.5.1. Steepest Edge Pricing

Steepest edge pricing is a rather expensive pricing rule that requires the solution of an additional system of linear equations involving the current basis matrix in every single iteration. The benefit is that the selected edge directions are typically leading to a smaller iteration count than other methods. The technique was introduced by Forrest and Goldfarb (1992) with an efficient update technique for the pricing weights. This paper also thoroughly describes different steepest edge variants and is highly recommended for further information on the topic.
In a nutshell, steepest edge pricing chooses the direction that has the most obtuse angle with the objective function and hence is expected to result in a short path to optimality.

### 3.5.2. Devex Pricing

At the most general level, devex pricing can be seen as an approximation of steepest edge pricing, saving computational cost per iteration when calculating the edge weights in exchange for a usually higher iteration count. This method was introduced
by Harris (1973). Interestingly, devex derives from the Latin term devexus meaning steep.

### 3.5.3. Shadow Pricing

This pricing rule is mostly relevant for theoretical purposes with respect to investigating computational complexity of the simplex algorithm as performed by Dadush and Huiberts (2019). SoPlex does not implement a shadow pricing rule, we still want to mention this technique for completeness.

### 3.5.4. Parallel Pricing Rules

There are also some variations of the above rules that can be employed for parallel implementations. In the original SoPlex publication (Wunderling, 1996), the parallel multiple pricing rule is described which inspects several pricing directions at the same time.

In Huangfu and Hall (2018) the authors also describe an elaborate pricing scheme that works well when executed in parallel.
The current version of SoPlex is entirely sequential and does not implement any parallel pricing rules.

### 3.5.5. Automatic Pricing Rule Selection

There have also been attempts to decide automatically which pricing rule might be the best for the current problem instance. We investigated three different applications for automatic algorithm selection for mixed-integer optimization (Hendel, Miltenberger, and Witzig, 2018): A multi-armed bandit implementation has been used to choose between devex pricing, steepest edge pricing and steepest edge pricing using non-exact initial weights. The results have been partly successful, demonstrating that SCIP using CPLEX as LP solver could benefit from slight performance improvements, while for SoPlex as LP solver this was not the case. Here, the criteria for a successful pricing rule was defined as the number of LP solves or processed branch-and-bound nodes in a fixed amount of time-the LP throughput. This setup is flawed with respect to determinism because the actual running time influences the solver's behavior. Implementing a deterministic clock is a major effort and usually involves tracking every single memory access as an alternative means of measuring the amount of performed work. Without this, the practicality of the approach is very limited.
Other applications for the multi-armed bandit approach inside SCIP's repertoire of algorithms have been proven to be more suitable to improve the performance. Especially the diving and large neighborhood search heuristics can benefit from this adaptive algorithm selection.

It is important to note that SoPLex implements a static heuristic pricing rule by default, that switches to steepest edge after 10000 iterations of devex have been performed. The rationale of this pricing scheme is that steepest edge is more expensive,
so we try to solve the model instance with the cheaper method and only switch over for harder problems. This is clearly a compromise that will rarely result in a minimal number of iterations when compared to the fixed methods. Still, experimental studies over very diverse test sets and parameter combinations have revealed that this a viable approach-especially when SoPLex is being used as LP solver within SCIP. We will go into more detail in Section 4.9.

### 3.6. Exploiting Sparsity

The majority of real-world problems from all kinds of applications and backgrounds rely on sparse data: The actual information is diminishing in comparison to the dimensions. Take a realistic supply chain management problem: To produce a certain product in a machine or factory, only a very small number of different resources are required, while the entire supply chain may comprise many more resources that are used in other contexts. This culminates in problem instances that have few non-zero variable coefficients in their constraints despite a high number of total variables.
We then speak of sparse data and the solvers need to implement specialized data structures to store and manipulate these values. It is not affordable to store all the zero values so SoPlex-just like any other modern solver-keeps index lists to store the mathematical position of the values while the values themselves are packed one after another to allow for fast access.
There are variations of this storage technique, like scattering the values into a larger array to facilitate adding new non-zero entries at the correct place.
Huangfu and Hall (2018) give a detailed description of a high performance simplex solver and also explain how to exploit the sparsity effects. The term hypersparsity was introduced for the linear programming context by Hall and McKinnon (2005) and has been extensively studied by the authors. In contrast to sparse input data, hyper-sparse is referring to sparse output data in certain computations in the simplex method, like the solutions of linear systems with the basis matrix or its transpose. Exploiting hyper-sparsity requires to assess where in the output data nonzero values may appear. This can significantly reduce the computational time for the affected operations and leads to an average speed-up of more than 5 for instances where the techniques can be applied.
In SoPLex version 2.2 (Gamrath, Fischer, et al., 2016), we implemented such a sparsityexploiting technique to accelerate the pricing process. This has been especially helpful for solving large-scale linear programs originating from supply-chain management optimization as demonstrated by Gamrath, Gleixner, et al. (2019). Figure 3.4 shows the number of necessary comparisons to determine the best pricing candidate for the next pivot. We need to scan the vector of basic variables for primal violations. Since only a subset of these violations have been modified during a simplex iteration, we can keep a dynamically updated list of candidates that can be much smaller than the basis size.

Despite all three methods shown in Figure 3.4 being mathematical equivalent, we
can see that a majority of comparisons can be avoided when only taking the updated violations into account-note that the the number of comparisons is depicted in logarithmic scale.

Figure 3.4.: Pricing statistics: The total number of current violations is several orders of magnitude larger than the number of updated violations per iteration.

Another application for exploiting sparsity is located in the PRICE step. Here, a matrix-vector multiplication needs to be performed. Depending on the sparsity of the multiplied vector, it can be beneficial to perform a row-wise rather than column-wise operation. This requires a row-wise storage of the constraint matrix $A$, which can be made available once without significant additional cost. What is more difficult to exploit is the fact that only the non-basic columns of $A_{\mathcal{N}}$ are required because the multiplying vector $\pi^{\top}=e_{j}^{\top} B^{-1}$ is the result of solving a linear system with $B=A_{\mathcal{B}}$ that involves the basic columns. We know that the resulting values will be 0 or 1 for those indices corresponding to basic variables. Hence, we can skip these operations and perform the multiplication only with $A_{\mathcal{N}}$ like it is presented in most text book descriptions. In the row-wise storage of $A$ we need to update the partitions of basic and non-basic columns after every iteration to have all non-basic values in a consecutive block in memory:

$$
A^{\mathrm{ROW}}=\left[A_{\mathcal{N}} A_{\mathcal{B}}\right]
$$

From personal communications with Julian Hall we have learnt that this additional overhead is usually worth it when weighed against the computational benefit of a shorter matrix-vector product.
Unfortunately, we were not able to speed up SoPLEx with an implementation of this modified PRICE multiplication. Koberstein (2005) also explains the different ways of computing the pivotal row as a result of either a matrix-vector-multiplication using the row-wise or the column-wise storage of $A$. They, too, admit that they were not able
to implement an efficient method of skipping and updating the unnecessary basic indices in the row-wise multiplication.

There are two different data structures implemented in SoPlex to support sparse vectors: SVector to store only the value and index pairs including some additional slot for the number of non-zeros. The other is a semi-sparse vector called SSVector with length equal to the actual dimension of the vector it represents and all non-zero elements at their corresponding position. Additionally, it also holds an index list of all non-zero entries to allow faster access to them and facilitate easy inclusion of new entries. What makes these data structures different from conventional sparse vectors is the fact that they use a tuple of value and index to store the data. Typically, there are two separate vectors for the values and for the indices, respectively. All underlying linear algebra sub-routines are built on these data structures and we suspect that an extensive rewrite is necessary to implement sparsity-exploiting algorithms more efficiently.

Finally, we would like to mention a rather straight-forward performance improvement technique that is especially useful for an LP solver within an MILP solver. It is common to have an incumbent integer feasible solution at some point during the solving process without the proof of optimality, so further branch-and-bound nodes need to be explored. For the corresponding LP relaxations, we can set an objective cutoff limit, because we are not interested in nodes that exhibit a worse dual bound than the objective value of the current incumbent. Those nodes can be pruned and the LP relaxation can be aborted at an early stage. To determine when the objective limit has been reached, we need to compute the current dual objective value at every iteration, which can be costly if not implemented carefully. Intuitively, one would just compute the new objective value based on the current values of the variables. We added an update method for the non-basic part of the objective function value to reduce the computation to only the basic part. This prevents repeated multiplications of the objective coefficients $c_{j}$ with those variables $x_{j}$ that did not change from the previous iteration. As typically only one non-basic variable changes its value during a simplex iteration, the complexity of computing the non-basic part of the objective value reduces from $\mathrm{O}(\mathrm{n}-\mathrm{m})$ operations to a constant factor.

This update is of course not necessary if only lower bounds of 0 and no upper bounds are present-in this case, it suffices to compute the basic part because $\mathrm{c}_{\mathcal{B}}^{\top} x_{\mathcal{B}}=$ $c^{\top} x$. In virtually all cases, though, the LP solver is faced with non-zero lower and finite upper bounds coming from domain propagation or branching decisions of the MILP solver or simply from upper bounds on integer and binary variables of relaxations of combinatorial optimization problems.

The above technique has a greater performance impact on larger instances, like the ones investigated by Gamrath, Koch, et al. (2015) and Gamrath, Gleixner, et al. (2019).

### 3.7. Persistent Scaling

The main goals of scaling are different for LP and MILP solvers. When dealing with MILPs, one typically scales to improve the integrality, that is, a constraint like the following can be easier handled after applying a row scaling factor of 3:

$$
1 / 3 \cdot x+2 / 3 \cdot y \leq 13 / 6 \quad \rightarrow \quad x+2 \cdot y \leq 6.5 .
$$

For LPs, on the other side, we employ scaling to improve the numerical features of the basis matrix to reduce the chance of introducing errors that might invalidate the correctness of our solutions.
An example in Gurobi's documentation demonstrates ${ }^{2}$ the effect of scaling by explicitly increasing the ranges of coefficients for a specific model instance. With further increasing detrimental scaling factors, the performance deteriorates until eventually the problem is incorrectly detected to be infeasible. This example shows that scaling affects not only the numerical conditions and the quality of the solutions but also the time and number of iterations required to solve a problem instance.
For an LP relaxation within an MILP solver, the simple way of using scaling-as well as presolving for that matter-is to apply it before the root node solving when there is no other information to be taken care of. After the root LP has been solved, all the data structures in the LP solver are transformed back into the original space to allow the MILP solver to easily apply modifications like bound changes or the addition of new LP rows.

Preserving the LP presolving transformations and translating all changes coming from the MILP solver into this transformed space is quite involved and likely too expensive to be useful. This is different for the less involved scaling, though, and our persistent scaling implementation proves that we can keep using scaled data even for later LP solves during the MILP solving process.
After the initial scaling has been computed, every change to the LP data and almost every information coming back from the LP solver needs to be scaled accordingly, to avoid having to scale the LP itself back and forth. Newly introduced columns or rows need to be assigned corresponding scaling factors, accordingly, extending the initial set of scaling factors stemming from the root LP. Additionally, results from computationally more involved operations like computing a certain row of the current basis matrix' inverse to generate cutting planes need to be un-scaled as well.
This extension to the API of SoPLEx has been implemented since version 3.0 and allows preserving the scaling factors throughout the MILP solving process without negatively impacting the overall performance. To be able to use this in SCIP, we also had to rewrite the LP interface entirely as it was previously accessing internal data structures directly, circumventing the dedicated API.
Persistent scaling for SoPlex has been enabled by default since SCIP version 4.0. Table 4.2 shows that about five more instances can be solved to optimality, five less

[^17]instances run into the time limit of one hour, and the average solving time is reduced by around $9 \%$. The number of simplex iterations is also positively affected by persistent scaling and goes down by about $15 \%$ while the average number of nodes is largely the same. We used SCIP version 6.0.2 for this experiment and manually disabled persistent scaling in SoPLex as there is no parameter in SCIP to control this directly.
In the following, we discuss how scaling is actually implemented for SoPlex and other simplex solvers.
When we talk about LP scaling we think of two scaling matrices $R$ and $C$. Those are diagonal square matrices of size $m$ and $n$ respectively. For all scaling factors we do not store and use the actual floating point values computed by the scaling methods but the closest base-2 exponents. This enables us to perform scaling operations without introducing any numerical noise because only the exponent of the value to scale is modified. The mantissa holding the digits remains untouched. Even though this procedure slightly modifies the actual scaling factors that are computed by the different methods, error-free computations are more crucial. Other benefits of this setup are reduced storage size for the factors (int instead of double or rational) and faster scaling operations since we only need to shift the exponent.
Besides the constraint matrix, also the upper and lower bounds of both columns and rows need to be scaled accordingly:
\[

$$
\begin{aligned}
R A C x^{\prime} & =R b \\
C^{-1} l \leq x^{\prime} & \leq C^{-1} u \\
x & =C x^{\prime}
\end{aligned}
$$
\]

Now, consider a scaled constraint matrix $A^{\prime}$ that is extended by artificial slack variables resulting in the matrix $\left(A^{\prime}, I\right)$. A basis matrix $B^{\prime}=\left[\left(A^{\prime}, I\right) P\right]_{1: m, 1: m}$ (with $P$ being a permutation matrix) for the scaled problem corresponds to the basis

$$
B=R^{-1}\left[\left(A^{\prime}, I\right) P\right]_{1: m, 1: m}\left[P^{\top} \tilde{C}^{-1} P\right]_{1: m, 1: m}
$$

In this equation, $\tilde{C}$ is of the form

$$
\left[\begin{array}{cc}
C & 0 \\
0 & R^{-1}
\end{array}\right] .
$$

We can see from those formulas that changes to the LP-as they frequently happen during MILP solving-need to be transformed carefully between the scaled and the original space. In case of the row representation it is additionally necessary to translate the values between the representations because the interface to SoPlex needs to provide the common column representation data of the basis matrix. This turns the seemingly simple task of storing scaling factors into a considerable implementational effort.

### 3.7.1. Scaling Methods

There are different ways to scale an LP and it cannot be easily determined which will lead to the best performance. Generally, we aim to move all coefficients of the problem as close as possible towards 1 or -1 . This is to reduce the numerical noise that is introduced when working with floating point numbers. Whenever we are performing operations using floating point arithmetic, there is a certain inexactness, mostly because the number of precisely representable values is rather small and we usually end up with the closest approximation to the real value. We trust the numbers only until the first nine or ten digits, although a double precision floating point number consists of 15 to 17 significant decimal digits (see also Table 6.1 for a comparison of different floating point precisions). Some operations like subtraction of equally large numbers can then push those not trust worthy digits to the front and cause the aforementioned numerical noise.
A related issue is introduced by numerical tolerances: Take a commonly used feasibility tolerance of $10^{-6}$ for example. Then, a simple constraint of the form

$$
200 \cdot x-y=0
$$

is feasible for values $x=1$ and $y=200$ but infeasible for $\tilde{x}=1+10^{-8}$ and $y=200$ with

$$
200 \cdot \tilde{x}-y=200.000002-200=2 \cdot 10^{-6}>10^{-6}
$$

This is despite the value of $\tilde{x}$ being even within the integrality tolerances of most solvers, so being treated as an integer value.
SoPLex supports different scaling methods that we will describe briefly:

Equilibrium Scaling. This scaling method simply divides all coefficients in a row or column by the largest one. This trivially guarantees that the largest coefficient is of absolute value 1 . There is still a degree of freedom in the order of the scaling, that is whether row or column scaling is applied first. Since this seemingly minor detail can lead to different outcomes as Example 1 shows, we employ a simple heuristic based on the row and column ratios to determine the order: The method that is applied first is the one that has the smaller maximal ratio of largest divided by smallest entry.
Two variants of this scaling method are implemented in SoPlex: Uni-equilibrium does only one pass, either over columns or rows, depending on the ratio, while biequilibrium always does both with the order being chosen by the ratio.

## Example 1.

$$
A=\left[\begin{array}{ll}
0.1 & 1 \\
10 & 1
\end{array}\right]
$$

Matrix A has a maximum row ratio of 100 and a maximum column ratio of 10 , when dividing the largest coefficient by the smallest in every row and column respectively.

$$
\text { row scaling first: } A^{\prime}=\left[\begin{array}{cc}
0.1 & 1 \\
1 & 0.1
\end{array}\right] \quad \text { column scaling first: } A^{\prime}=\left[\begin{array}{cc}
0.01 & 1 \\
1 & 1
\end{array}\right]
$$

Geometric Scaling. This method computes scaling factors based on the square root of the product of the largest and the smallest value in each respective row or column. There is also an extension called iterated geometric scaling that performs several of such sweeps over the constraint matrix to achieve a more balanced result. A maximum iteration count of 8 has proven to be enough-subsequent sweeps do not improve the result considerably.

Least Squares. This is the most sophisticated and also most expensive scaling variant. It has been implemented for SoPLex version 3.1 (Gleixner, Eifler, et al., 2017). The goal of least squares scaling is to achieve the best possible numerical stability of $A$ with respect to Gaussian elimination or LU factorization. This method is also known as Curtis-Reid scaling (Curtis and Reid, 1972). Similar to equilibrium scaling it tries to even out outliers and smooth all entries of the matrix. Unlike the simpler methods this is carried out by solving a least squares problem:

$$
\begin{equation*}
\min \sum_{A_{i j} \neq 0}\left(\log _{2} A_{i j}-\rho_{i}-\gamma_{j}\right)^{2} \quad, i \in\{1, \ldots, m\}, j \in\{1, \ldots, n\} \tag{3.11}
\end{equation*}
$$

The resulting $\rho$ and $\gamma$ values are rounded and define the scaling factors as $\mathrm{R}_{\mathrm{ii}}=2^{-\left[\rho_{i}\right]}$ and $\mathrm{C}_{\mathrm{jj}}=2^{-\left[\gamma_{j}\right]}$ respectively.

We can solve the least squares problem 3.11 using the conjugate gradients method (Hestenes and Stiefel, 1952) applied to this system of linear equations:

$$
\begin{aligned}
& M \rho+E_{A} \gamma=\left[\sum_{j} \log _{2} A_{1 j}, \ldots, \sum_{j} \log _{2} A_{\mathfrak{m j}}\right]^{\top} \\
& E_{A}^{\top} \rho+N \gamma=\left[\sum_{i} \log _{2} A_{i 1}, \ldots, \sum_{i} \log _{2} A_{i n}\right]^{\top}
\end{aligned}
$$

Here, $E_{A}$ is a 0-1-matrix with the same non-zero pattern as $A$ whereas $M$ and $N$ are diagonal matrices that contain the numbers of non-zero entries for each row and column of $A$ respectively.

Computing these least squares scaling factors is computationally more expensive than the other methods but still does not impair the performance on most instances.

Elble and Sahinidis (2012b) compare different scaling methods specifically for scaling linear programming problems. Their main result is that equilibrium scaling provides the best results under the assumption that computational costs cannot be neglected. SoPlex uses equilibrium scaling by default. When applied inside SCIP, users
can enable aggressive scaling to switch to least squares for numerically more challenging problem instances.

Note that interior point solvers are less susceptible to scaling as explained by Anderson et al. (1996).

### 3.8. LU Factorization and Update

We will not go into detail on how to implement an efficient and numerically robust LU factorization including the necessary update methods for the simplex algorithm. As this is a crucial ingredient in any simplex code, we give an overview of the standard methods and some fairly recent developments in this field.

In a nutshell, our task is to solve two systems of linear equations in every iteration of the simplex algorithm. Both involve the current basis matrix $B$ while one uses the transpose $\mathrm{B}^{\top}$ :

$$
\begin{array}{lc}
\text { BTRAN: } & B^{\top} z=e_{p} \\
\text { FTRAN: } & B \hat{a}_{q}=a_{q}
\end{array}
$$

These two operations are historically called FTRAN and BTRAN-short for forward transformation and backward transformation-and hark back to the very first computer implementations using punch cards to encode the machine instructions: As BTRAN uses the transpose of the basis matrix, its implementation is equivalent to inserting the punch card backwards. It is interesting to see this naming convention still being present and used even today in state-of-the-art high-performance simplex implementations.

For solving these two systems of linear equations, a prior LU factorization of $\mathcal{B}$ has been proven highly useful and efficient:

$$
\begin{array}{lll}
\text { factorize: } & & B=L U \\
\text { solve: } & L U X=b \Rightarrow L y=b \text { and } U x=y
\end{array}
$$

Note that, while this factorization is less numerically stable than for example a QR factorization, that is, a factorization into an orthogonal matrix $\mathrm{Q}\left(\mathrm{Q}^{\top}=\mathrm{Q}^{-1}\right)$ and an upper triangular matrix $R$, the sparsity preservation and update functionalities of the LU factorization are more important for application in the simplex method. The two resulting systems involve lower and upper triangular matrices L and U that facilitate a straightforward solution process as shown in Algorithm 3.1.
The procedure for U can be carried out analogously, starting from the bottom and moving upwards. Due to the non-unit diagonal of $U$ we need to add a multiplication with $1 / \mathrm{u}_{\mathrm{ij}}$ to achieve the correct result, see Algorithm 3.2.
As we can see from those algorithms, sparsity in the input data, that is, in the respective right-hand sides and in the triangular matrices, can already be used to skip certain operations. This is only scratching the surface of what is possible to speed up these computations as demonstrated by Hall and McKinnon (2005). One important

```
Algorithm 3.1 lower triangular solve: FTRAN-L
Input: \(\mathrm{b} \in \mathbb{R}^{\mathrm{m}}\) and \(\mathrm{L} \in \mathbb{R}^{\mathrm{m}, \mathrm{m}}\) lower triangular and unit diagonal
    \(\mathrm{y} \leftarrow \mathrm{b}\)
    for \(\mathfrak{j} \in\{1, \ldots, m\}\) do
        if \(y_{j} \neq 0\) then
            for \(i \in\{j+1, \ldots, m\}\) with \(L_{i j} \neq 0\) do
                        \(y_{i} \leftarrow y_{i}-L_{i j} y_{j}\)
        end for
        end if
    end for
    Return: y with L y \(=\mathrm{b}\)
```

```
Algorithm 3.2 upper triangular solve: FTRAN-U
Input: \(x \in \mathbb{R}^{m}\) and \(U \in \mathbb{R}^{m, m}\) upper triangular
    \(x \leftarrow y\)
    for \(\boldsymbol{j} \in\{\mathfrak{m}, \ldots, 1\}\) do
        if \(x_{j} \neq 0\) then
            \(x_{j} \leftarrow 1 / u_{j j} x_{j}\)
            for \(i \in\{j-1, \ldots, 1\}\) with \(\mathrm{U}_{\mathrm{ij}} \neq 0\) do
                        \(x_{i} \leftarrow x_{i}-U_{i j} x_{j}\)
            end for
        end if
    end for
    Return: \(x\) with \(U x=y\)
```

aspect is the accurate prediction of where the so-called fill-in happens. These are non-zero elements in the solution vector that do not already have a corresponding non-zero entry at the same position in the right-hand side vector. Graph algorithms applied to the non-zero structures of the triangular matrix and the right-hand side can be used to determine these positions. Of course, this introduces some significant overhead and needs to be adaptively activated depending on the sparsity of the current system. SoPLEX only implements a subset of these techniques resulting in a worse performance than other solvers when dealing with highly sparse model instances.
In every iteration of the simplex method, we update the basis matrix by exchanging a column vector with one of the non-basic columns $a_{q}$ of the constraint matrix $A$ or a unit column. This can be formalized as

$$
\tilde{B}=B+\left(a_{q}-B e_{p}\right) e_{p}^{\top}
$$

with the incoming column $a_{q}$ replacing the pth basic column in $B$ and the basis itself is updated to $\tilde{\mathcal{B}}=\mathcal{B} \cup\{q\} \backslash\{p\}$. Every such update needs to be integrated into the factorization to properly represent the current basis matrix and in regular intervals a fresh factorization is computed to clean up the accumulated updates. Huangfu and Hall (2015) provide a survey of the standard methods and several variants further improving speed and efficiency. SoPlex implements both the rather straightforward method of representing the updated LU factorization as series of rank-one matrices called the product-form update developed by Dantzig and Orchard-Hays (1954) as well as the more technical Forrest-Tomlin update as described by Forrest and Tomlin (1972) and Suhl and Suhl (1993).

For a comprehensive overview of all the different basis inverse update techniques we refer to Elble and Sahinidis (2012a).

### 3.9. Iterative Refinement

The term iterative refinement was coined by Wilkinson (1963) for a more accurate solution of systems of linear equations. The main idea is to solve multiple auxiliary systems of linear equations that iteratively minimize the error in the solution of the original problem.
This technique can be applied to linear programming using the simplex method in an elegant way as demonstrated by Gleixner, Steffy, and Wolter (2012), Gleixner (2015), and Gleixner, Steffy, and Wolter (2016). The authors exploit the discrete nature of the simplex basis to perform subsequent optimizations of scaled versions of the original problem that aim for minimizing the error of the solution. This is achieved by using higher-precision arithmetic like in other simplex implementations, see for instance QSOPT_EX (Espinoza, 2006). The main advantage, though, is that only very few iterations using expensive computations in rational arithmetic are necessary to improve upon the initial solution provided by the standard solver in double precision arithmetic.

Figure 3.5.: LP iterative refinement to compute more accurate solutions

The authors came up with a very nice visualization of the technique as shown in Figure 3.5 , where the refinement LPs can be seen as zoomed-in versions of the original formulation. While a potential bound or optimality violation is not visible in the first depiction, we can spot the infeasibility in the scaled version on the right.

### 3.10. Decomposition Based Dual Simplex

The decomposition based dual simplex (DBDS) is a method to exploit and avoid dual degeneracy in a given linear programming problem to reduce the number of iterations until optimality (Maher, Fischer, et al., 2017). Its core idea is based on the work of Elhallaoui et al. (2011), that introduces a column generation approach to deal with primal degeneracy, called Improved Primal Simplex Algorithm. This is especially helpful for solving instances of set partitioning problems. The method implemented in SoPlex can be seen as the dual version of this approach. It decomposes a problem that shows dual degeneracy at the current basis into a reduced and a complementary problem, that are non-degenerate. This reduces the total number of iterations, since fewer degenerate steps are taken.

DBDS relies on the row representation of the basis and is an iterative algorithm that keeps adding rows to the reduced problem until all primal violations are resolved.
In its current state, DBDS is an experimental algorithm that does not outperform the default simplex method in SoPLEX in terms of time or iterations on general problems. There have been significant reductions in iterations on certain problem instances which shows that the method has potential as a problem specific implementation. It is unclear, though, what characteristics of a problem make it suitable for DBDS. The amount of degeneracy alone is not enough as experiments by Maher, Fischer, et al. (2017) have shown.

### 3.11. Performance Variability

The term performance variability was coined by Danna (2008) and further investigated by Koch, Achterberg, et al. (2011). Generally speaking, it refers to how much a seemingly insignificant change in the solver or the model data can introduce a drastic performance fluctuation. It is a stability measure that often helps assessing whether the results obtained on one machine will be reproducible on a different machine. Integer programming has been the focus of the mentioned works, while the class of linear programming problems is believed to be less impacted by this effect. We show how much the solving times and iteration counts vary after choosing a different random seed in SoPLex. The random seed determines the sequence of generated (pseudo) random numbers that are used throughout the code. This can be seen as a minimal change to impact the algorithmic behavior and is frequently used to stabilize performance benchmarks carried out by SCIP.
To measure performance variability, Koch, Achterberg, et al. (2011) use the variability score VS for every single instance in the different experiments:
Definition 3 (Variability score).

$$
V S(t, k)=\frac{1}{\sum_{i=1}^{k} t_{i}} \cdot \sqrt{\sum_{i=1}^{k}\left(t_{i}-\frac{\sum_{i=1}^{k} t_{i}}{k}\right)^{2}}
$$

$\mathrm{VS}(\mathrm{t}, \mathrm{k})$ measures how strongly a set of observations $\mathrm{t}_{\mathrm{i}}, i=1, \ldots, k$ differs from one another.

From Figure 3.6 we see that there is actually only a small number of instances that are sensitive with respect to the random seed choice. For those extreme cases, the solving times can vary by a factor of almost 10, as listed in Table 3.3. The vast majority of instances, though, does not show a strong performance variability.

### 3.12. Performance Impact of Selected Features

To assess how the mentioned features impact the performance of SoPlex we analyze computational experiments on the allLP test set. Table 3.4 compares default settings and runs with one of those features disabled and aggregate the results over three different random seeds. The iteration ratio column covers only those 1336 instances that have been solved by all settings.
We see that for all features except quick start steepest edge pricing, it is worthwhile to use default settings when aiming for the best solving time. There is a strong impact on the number of iterations when using a different pricing method that also leads to different solving times. On this test set, that includes many pure LP problems besides relaxations from MILP instances, we might as well use quick start steepest edge pricing for a slight performance increase.

In Chapter 4, Table 4.2, we compare how these LP improvements carry over to SCIP's performance on the MIPLIB 2017 benchmark set.

| instance | iterations |  |  |  | time |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  | max | min | ratio | VS | max | min | ratio | VS |
| cdma | 260271 | 56336 | 4.6 | 0.3 | 158.2 | 16.2 | 9.3 | 0.4 |
| cont1 | 107902 | 41395 | 2.6 | 0.3 | 3600.0 | 1570.2 | 2.3 | 0.2 |
| dbic1 | 217952 | 64009 | 3.4 | 0.2 | 1132.7 | 189.3 | 6.0 | 0.3 |
| mzzv42z | 35020 | 16664 | 2.1 | 0.2 | 15.9 | 5.4 | 2.6 | 0.3 |
| neos-2075418 | 116602 | 46961 | 2.5 | 0.3 | 698.4 | 95.3 | 7.3 | 0.6 |
| neos-3402454 | 57951 | 16023 | 3.6 | 0.4 | 3600.0 | 609.0 | 5.9 | 0.5 |
| neos-777800 | 11398 | 2398 | 4.8 | 0.3 | 1.3 | 0.3 | 1.8 | 0.3 |
| rlfdual | 12298 | 8317 | 1.5 | 0.1 | 5.7 | 1.3 | 2.9 | 0.3 |

Table 3.3.: allLP instances with a time or iterations ratio larger than 2.5 when solved with SoPLEX 4.0.2 and a different random seed value. The test set contains 1382 instances, 1336 of which can be solved to optimality.

| setting | wins | losses | iter ratio (all opt) | time ratio |
| :--- | :---: | :---: | :---: | :---: |
| no presolving | 398 | 390 | 1.49 | 1.25 |
| column representation | 277 | 375 | 1.08 | 1.08 |
| row representation | 336 | 437 | 1.06 | 1.43 |
| devex pricing | 281 | 431 | 2.30 | 1.90 |
| qsteep pricing | 502 | 299 | 0.78 | 0.96 |
| no bound flips | 425 | 308 | 1.17 | 1.07 |
| Curtis-Reid scaling | 303 | 458 | 1.12 | 1.09 |
| solution polishing | 247 | 424 | 1.05 | 1.03 |

## Chapter 4

## Impact of Linear Programming in MILP

There are many situations in the MILP solving process where the solution of an LP is required. The most prominent one is arguably the root LP. This initial relaxation provides a first so-called dual bound for the MILP and determines the first branching decision-given that integer variables with fractional solution values are present. Often, it takes up a significant part of the overall solving time. During the tree search, on the other side, LP solutions of the branch-and-bound node relaxations can be obtained a lot faster with the help of previously processed nodes. This is mainly due to the warm-starting capabilities of the simplex algorithm. Here, an existing basis, for example from the parent node, can be used as a dual feasible starting basis for the next sub-problem and very few iterations suffice to solve it to optimality.

Dual feasibility is maintained throughout the tree search if only variable bounds or constraint sides are tightened. Table 4.1 lists the different problem modifications and whether they maintain primal or dual feasibility of the current basic (optimal) solution.

| problem modification | primal feasibility | dual feasibility |
| :--- | :---: | :---: |
| additional variables | $\checkmark$ | - |
| additional constraints | - | $\checkmark$ |
| modified objective coefficients | $\checkmark$ | - |
| modified right-hand sides | - | $\checkmark$ |
| modified matrix coeffs (basic variables) | - | - |
| modified matrix coeffs (non-basic vars) | $\checkmark$ | - |

Table 4.1.: Feasibility implications of different types of LP problem data modifications
While these two types of LPs-root LP and node relaxations-already cover the general branch-and-bound scheme, there are many sophisticated techniques that also rely on LP solutions, like heuristics, cutting plane generation or conflict analysis.

All this suggests that LP solving performance has got a major influence on the overall MILP solving performance. In this chapter we will investigate this impact and also show the fundamental differences of the two scenarios LP and MILP solving.
Koch, Martin, and Pfetsch (2013) mention the peculiar fact that the pure LP or simplex performance does not translate to a comparable MILP solving performance. This effect can also be observed for commercial solvers like GUROBI: A ~20\% LP performance gain of version 9.1 compared to the previous version only resulted in a $\sim 5 \%$ speed-up for solving MILPs. We want to investigate this unintuitive discrepancy using SCIP and its capability to plug-in various LP solvers.

Beside the widely used approach of using either a variant of the simplex method or the barrier algorithm internally, there are also other ways of computing feasible solutions to MILPs that we want to mention briefly: The commercial solver LocalSolver ${ }^{1}$, for example, is using fast heuristics and a variety of combinatorial methods to find feasible solutions to MILPs without necessarily proving optimality. This is especially relevant and useful for model instances that have a very difficult and time consuming LP relaxation to solve or for very specific problem types. We will not go into detail for such approaches because they are fundamentally different from the LP-based branch-and-cut approach and usually do not provide a proof of optimality. Additionally, there are heuristic methods implemented in conventional MILP solvers that do not require an LP solution or even a dual bound in the first place.
We are only aware of few publications that are concerned with LP and MILP performance comparisons of different solvers. Meindl and Templ (2012) discuss the use of different LP solvers within SCIP and benchmark this against other implementations-it does not go into much detail, though, and mainly provides an overview.

In the following sections, we want to point out the different areas where LP solutions are most prominently used during the MILP solving process. To give a rough idea of the individual components that directly depend on the availability of LP solutions, we took the infamous "SCIP flower" and colored all buds red that actively solve new LPs (Figure 4.1).

### 4.1. Implementational Details

SCIP has an open interface to connect to many different LP solvers that are treated as black box. This is implemented through two main layers in the SCIP code: One is the internal LP object that represents the current relaxation and keeps information on pending bound changes and several other pieces of information and statistics. This layer is oblivious of the actual LP solver that is connected to the second layer-the LP interface or LPI. This interface implements methods to pass data to and from the connected LP solver and controls the LP solving process. Since the LP solver relies on its own data structures it cannot use the problem data that is stored in the LP object. Instead it has to construct a new copy of the relaxation and every modification to SCIP's

[^18]

Figure 4.1.: Abstract visualization of SCIP's components with those colored in red that heavily rely on LP solutions or trigger new LP solves. The image depicts version 3.2 of SCIP and is only intended for the purpose of illustration and makes no claims of being complete.
internal LP needs to be transferred before initiating a new solve or re-optimization.
Naturally this setup leads to some overhead both memory- and performance-wise when compared to an implementation that uses an integrated LP solver as is the case for most other especially commercial MILP solvers. This is also one reason why SCIP will never reach the same level of performance and efficiency.
On the other hand, we can use this versatile interface to investigate how different LP solvers impact the overall optimization process.
We are aware that SCIP is not the only option to compare different LP solvers within a branch-and-bound based MILP code. CBC of the COIN-OR Foundation ${ }^{2}$ is arguably the most popular alternative. Still, we do not include this solver framework into our experiments because of its considerable weaker performance on general MILP problems when compared to SCIP and especially when competing against commercial MILP solvers.

### 4.2. Root and Node LPs

We have already mentioned in Chapter 1 that the initial LP relaxation is one of the most time-consuming aspects of many MILP instances. On the other hand, there are also instances with easy-to-solve LP relaxations that still require a lot of time to find the optimal solution because of excessively large branch-and-bound trees.

From personal experience, we can attest that most practical MILPs fall into one of the three categories:

- Easy instances that can be solved quickly to optimality. The definition of quick is of course subject to the actual application at hand and may differ quite a lot from case to case.
- Instances that require a lot of time to process the root LP but can be solved to optimality with a small search tree or even just in the root node.
- Instances that do not pose any difficulties to the LP solver but make it very hard to find good feasible solutions or prove optimality because of a very large branch-and-bound tree. Often, such instances have a weak formulation, that is, the linear relaxation is not helping much in guiding the search towards optimality and therefore results in a large number of nodes.

Of course, there are also instances that have a very difficult LP relaxation and a very large branch-and-bound tree; due to this inconvenience, they are usually transferred back to the modeling stage to find alternative formulations or to split up the problem into smaller, more manageable pieces.

In Figure 4.2 we show the amount of time that is spent solving LPs during the MILP solving process. This scatter plot shows how different the LP time fractions are distributed among the instances and that they do not correlate with the overall solving

[^19]time-independent of the LP solver used. The widely scattered fractions for those instances that are exhausting the time limit, visible as a vertical wall at the one hour mark, are a good indicator for that. Only with CLP as LP solver, a number of instances break this barrier. This is because of a less responsive termination behavior after the time limit has already been exceeded. For a more detailed breakdown of the different types of LPs that are solved, please refer to Figure 4.5.

Figure 4.2.: Fraction of time spent solving LPs during MILP solving. We compare different LP solvers in SCIP on on the MIPLIB 2017 benchmark set, including instances that are not solved within one hour. We can see that with CLP, the time limit is not always respected.

Typically, we solve MILPs without any starting information, so the root LP needs to be solved from scratch. This is in stark contrast to practically every other LP solve that needs to be performed afterwards. Here, we can draw on useful data to warmor hot-start the optimization of the relaxations.

Warm-starting, usually refers to providing the simplex algorithm with a feasible basis that is ideally already close to being optimal, that is, only a small number of iterations are necessary to reach it. This is the case during the cutting phase: whenever a new cut is added, the current basis remains dual feasible, but the dimension of the basis matrix is different and often a new LU factorization needs to be computed. See Section 4.5 for additional information.

Hot-starting on the other hand, denotes a similar process that leaves the factorization intact and allows an even faster re-optimization of the new LP. The simplest use-case is the actual branching process as detailed in Section 4.3: fixing a binary variable to either 0 or 1 or restricting the domain of an integer variable by including a disjunction to cut off the current node's LP solution. Since this is only further restricting the feasible domain of the active LP just like in the cutting step, the dual feasibility of the basis is preserved. Additionally, the basis matrix is not modified, the factorization remains also valid.

Here, we silently assume that the simplex method is used to solve those node LPs. While this is the most practical approach due to the mentioned warm- and hot-starting effects, there are also instances that are solved significantly faster using the barrier method and even the node LPs profit from using this method over the simplex algorithm. Berthold, Perregaard, and Mészáros (2018) give an overview of the other lesser known applications for an interior point or barrier solver when dealing with an MILP, including primal heuristics and presolving techniques that would not be possible with the simplex method.

Unfortunately, if both approaches are viable, it is extremely difficult to predict which method will be better suited for a specific LP or MILP instance. Usually, some heuristic guess is made based on the dimensions and sparsity of the problem matrix-larger problems generally being solved faster with the barrier. In case enough computing resources are available in form of parallel threads, most solvers actually run several methods concurrently when solving the root LP or a similar problem without useful warm-starting information to kick-start the simplex. This inability to reliably predict a certain method's performance even extends into whether to use the primal or dual variant of the simplex, so these are also often run in parallel. Typically, commercial MILP solvers use the available computing threads for other tasks like parallel node processing or running heuristics. So this concurrent approach is only feasible for the root node when the progress is largely dependent on the initial LP solution and not enough other work can be parallelized, yet.

Figure 4.3 shows how using either the simplex or barrier method affects the fractionality, iterations, and solving time of the root LPs of the MIPLIB 2017 benchmark set. We have been performing this experiment with MOSEK as LP solver because the other applicable solvers (CPLEX, GUROBI, and XPRESS) have been reporting too many spurious iteration counts in SCIP. The qualitative results for the time and fractional-
ity comparisons have been similar, though. Please refer to Table B. 5 for the detailed results.

Figure 4.3.: Comparison between different LP solving methods in SCIP 6.0.2 using MOSEK 8.1.0.21 as LP solver (single-threaded). Barrier iteration counts are largely independent of the problem sizes, whereas the simplex iterations increase with growing dimensions. The respective solving times remain very comparable across the MIPLIB 2017 benchmark set. The right plot shows the difference in root LP fractionality when using either the simplex or the barrier method. Performing the additional crossover step reduces the fractionality dramatically.

We have also been running various experiments with the different LP solving methods in SCIP but decided that the results were too unreliable and unstable to make further conclusions. SCIP-at least in version 6.0.2-should mainly be used with the simplex method to solve the occurring LP relaxations.
In Figure 4.4 we can see that with CLP there is a large number of instances whose solving time is spent entirely or almost entirely by the LP solver. With SoPlex and MOSEK, there is still a strong tendency towards the right-most third of the histogram, meaning that a significant portion of the instances' solving time is spent by the respective LP solver. CPLEX, GUROBI, and to a lesser extent also XPRESS display a more balanced time distribution and consequently, allow more time to be spent in SCIP itself instead of computing an LP solution.
The bad performance of CLP is likely due to the extremely high number of unstable resolves, as depicted in Figure 4.5. This instability detection is based on violations

Figure 4.4.: Histogram depicting the fraction of time spent by the LP solver during MILP optimization. The bars depict how often a certain fraction of the total solving time is consumed by the respective LP solver. This also includes instances from the MIPLIB 2017 benchmark set that exhausted the one hour time limit.
in the LP solutions. Such solutions are then rejected by SCIP and another try with different parameters or tolerances is initiated. If necessary, the warm-start basis is even thrown away in hopes of avoiding numerical difficulties when performing a fresh start. This also explains the poor performance of CLP in SCIP and we should take those results with a grain of salt. Interestingly, with XPRESS there is not a single LP that is rejected by SCIP, indicating a very stable implementation of the solver.

### 4.3. Branching Rules

Branching Rules are the different strategies of choosing the variable to branch on in the branch-and-bound process. Usually, we select one of the integer or binary variables, say $x_{i}$, that has a fractional value $\check{x}_{i}$ in the LP relaxation's solution of the current node. Forcing this variable $x_{i}$ to be either $\leq\left\lfloor\check{x}_{i}\right\rfloor$ (the down branch) or $\geq\left\lceil\check{x}_{i}\right\rceil$ (the up branch) invalidates the current LP solution in both child nodes and reduces the search space in the new subproblems. Figure 4.6 provides a visual aid. There are many different strategies for selecting the next variable, often strongly affecting

Figure 4.5.: Distribution of the different types of LPs that need to be solved during an MILP optimization on MIPLIB 2017 benchmark instances with SCIP in one hour. Only optimally solved instances are included. Noteworthy is the very high number of unstable LP solves with CLP and the relatively large number of primal LP solves with CPLEX. Gray markers represent outliers with respect to the interquartile range.
the overall number of nodes visited in the tree and the total time to optimality. The various branching rules can also involve very time-intensive computations to reduce the number of nodes so we need to be careful when comparing their efficiency as explained by Gamrath and Schubert (2018). As an example, imagine a branching rule that solves multiple LPs in an internal subroutine, essentially hiding these processed nodes from the global node counter.
In the following paragraphs, we give a short overview of the most popular and well-known branching rules that are available in typical branch-and-bound solvers for MILPs.

Most infeasible branching This branching rule is a very simple strategy that chooses the variable that violates its bounds the most to branch on, that is, the variable that

Figure 4.6.: Visualization of the branching procedure with the MILP imposed by intersection of the blue region and the orange integrality conditions. LP solution $\check{x}$ on the left is removed from the two subproblems on the right that include restrictions in horizontal direction: $x_{i} \leq\left\lfloor\check{x}_{i}\right\rfloor$ and $x_{i} \geq\left\lceil\check{x}_{i}\right\rceil$, respectively. The resulting LP solutions $\check{x}_{-}$and $\check{x}_{+}$are integer feasible and $\check{x}_{+}$is the optimal solution.
is closest to 0.5 in the LP relaxation's solution. This sounds like a good idea on paper because it is very easy to compute and one might think that the less violated variables may become feasible on their own when forcing the other ones onto one of their bounds. Additionally, this should have a larger impact on the LP relaxations in the new child nodes. In practice, though, Achterberg, Koch, and Martin (2004) showed that this branching strategy turns out to be as good as random branching, showing once more how intuition can fail us in mathematical programming.

Pseudo-cost branching This is a more involved branching rule that was first described by Bénichou et al. (1971). It basically tracks the objective gain of every up and down branch each variable has already taken part of. This provides a history of efficacy for each variable that is used to compute a score to determine the next variable to branch on. There are multiple variants of how exactly to compute the score and weigh the past results and we refer to Achterberg, Koch, and Martin (2004) for further details.

Strong branching This branching scheme is very expensive but often results in a significantly reduced tree size. The main idea here is to solve multiple LPs corresponding to some or even all available branching candidates. This provides a good overview of the actual effect of branching on those variables and we can choose the variable based on some score that is determined by the solution of the respective LP solutions. To save time, most implementations do not inspect all available fractional candidates and also limit the number of simplex iterations in each LP solve-the re-
sulting scores are usually still very informative. To push this to an extreme, there are even approaches that merely run the first simplex iteration with the newly modified variable until the ratio test is done. The resulting step length is then used to get some idea about the corresponding pivot or basis change without actually executing it. That way, practically all data structures are left unchanged and many variables can be probed without investing too much time.
Running the branching rule without those limits is commonly referred to as Full Strong Branching. For more information, we refer to the original authors Applegate et al. (1995) and to Gamrath (2014) for an extension that also includes domain propagation within the branching candidates' LP solves.
One trait that is present in all strong branching implementations is their dependency on quickly available LP solutions. In SCIP this is realized by backing up the current basis information before starting the strong branching process so the dual simplex can start from that base and can be reset just as quickly to the initial state right before strong branching.

Inference branching Especially when dealing with a feasibility problem, that is, a model instance with a constant objective function, we cannot rely on improvements or changes in the dual values of the branching candidates. Instead, we can use a technique from the field of Constraint Programming and satisfiability problems: inference branching tracks the amount of deductions and implications that a branching candidate entails. Hence, branching on a variable with a high inference rate is supposed to achieve a greater reduction of the remaining solution space to explore.

Hybrid branching To avoid the expensive cost of strong branching and to get around the missing historic information of pseudo-cost branching in the early stages of the tree search, we can also combine both ideas and initialize the pseudo-cost values by running strong branching for the first few levels of the tree search. Further down in the tree, pseudo-cost branching is used to speed up the branching decisions. In addition to that, we can also include the inference score in case the information gained from the objective is not meaningful enough.

Reliability branching This branching rule is a further extension of hybrid branching and uses strong branching not only to initialize the pseudo-costs but also whenever these pseudo-costs are not reliable, that is, when not enough previous branching data exists to make an informed decision. Achterberg, Koch, and Martin (2004) show how these last four branching rules are related to each other and provide extensive computational data that shows how modifying the parameters of these rules impact the solving time as well as the tree size. A version of reliability branching is still the default branching rule in SCIP.

Neural branching This is a very recent development extending the classical branching schemes. In Nair et al. (2020), the authors show how the branching decision can be improved significantly by collecting branching scores for possible candidates in a full strong branching manner. As explained above, this requires solving a lot of LPs-one for each candidate-so the benefit of better branching decisions will be overshadowed by the excessive computational overhead of the LP solves. Instead, the authors opted for approximated LP solutions and employed a GPU-accelerated ADMM method (Alternating Direction Method of Multipliers, Boyd et al., 2011) to solve these LPs in parallel to generate the learning data. This Neural Branching approach works because determining a good branching candidate does not rely on exact LP solutions as has been already discovered by Achterberg, Koch, and Martin (2004). So, machine learning appears to be a good fit to estimate the branching scores and the paper provides computational evidence.

In summary, we see that (most) branching rules heavily rely on LP solutions to determine the next variable to branch on. While we can expect the smallest tree using the full strong branching approach, the additional cost of computing all these LP solution need to be accounted for to still achieve an overall speedup. This balancing act is what makes branching rules an interesting field of MILP solving that is still in the focus of active research and development and further advances can be expected in the years to come.

Dey et al. (2021) provide a recent analysis regarding the performance of (full) strong branching for a variety of combinatorial problem classes using randomly generated data. One of the most interesting findings is that full strong branching keeps the search tree within at most twice the number of nodes of the optimal, that is, the smallest search tree for any of the analyzed instances. The authors also note that the underlying LP solver plays an important part, especially regarding whether an integer or fractional LP solution is returned (given that there is an integer LP solution at the current node). One important aspect that is largely ignored in this paper is the amount of work necessary to actually carry out a full strong branching approach throughout the entire MILP solving process-they focus on the size of the tree instead of the solving time.

### 4.4. Node Selection

Every branching decision typically creates two new subproblems. Naturally, the question arises which node to process next. In addition to the two child nodes at the current node, we may also decide to switch to another open node somewhere else in the tree. There are different strategies in choosing the next node to continue the search and they generally need to satisfy the following two goals:

1. Improve the primal bound by quickly finding new incumbent solutions.
2. Improve the dual bound by further exploring nodes with a very small LP objective value.

The first strategy tends to favor deep dives into the tree because we expect to find integer feasible solutions easier after many branching decisions and possibly variable fixings have been already performed. The second strategy on the other hand will explore the tree in a breadth-first manner to work on those nodes that have a very small dual bound and are typically found close to the root node where less restrictions have been imposed on the LP.

Intuitively, we want to combine both approaches to improve the dual bound while also finding new primal solutions as soon as possible. SCIP provides several different node selection rules and uses a method called best estimate that assesses how likely new solutions will be found in the corresponding subtree by calculating a measure based on pseudo-cost values and the current LP objective value. We refer to Achterberg (2007) for detailed descriptions.
The chosen node selection variant has a smaller impact on the MILP solving performance than other parameters, like for example the branching rule, and just using the straightforward best bound approach is still a viable choice.

Note that in Chapter 6, we are using breadth-first search as node selection rule to collect more balanced statistics across the entire tree. Otherwise, we might have to deal with deeper plunges down the tree without visiting other nodes of the same depth.

### 4.5. Cutting Planes

The idea of cutting in MILP solving is based on the idea of separating the current LP solution from the convex hull of the integer feasible points of the MILP as visualized in Figure 4.7: Let $\check{x}$ be a solution to the LP relaxation of MILP (1.1). Then, a valid cutting plane can be defined as a pair $\left(\alpha, \alpha_{0}\right) \in \mathbb{R}^{n+1}$ such that for all $x=\left(x_{1}, \ldots, x_{n}\right)$ in the convex hull of all integer feasible points of MILP (1.1) the following hold.

$$
\sum_{j=1}^{n} \alpha_{j} x_{j} \leq \alpha_{0} \text { and } \sum_{j=1}^{n} \alpha_{j} \check{x}_{j}>\alpha_{0} .
$$

Finding such a pair ( $\alpha, \alpha_{0}$ ) is also known as the separation problem for $\check{x}$, as the corresponding hyperplane separates the point $\check{x}$ from the convex hull.
Typically, this requires a valid LP solution in the first place to have a point to separate from the convex hull. Additionally, many cutting plane methods also directly use the current simplex basis to compute valid inequalities that cut off the corresponding LP solution.

Such cuts are known as Gomory cuts or Gomory fractional cuts.
Assuming an IP problem $\left\{\min ^{\top} x \mid A x=b, x \in \mathbb{N}\right\}$ and applying the fractionality operator $f(a):=a-\lfloor a\rfloor$, we can use the following transformation to generate a valid

Gomory inequality from the ith row:

$$
\begin{align*}
\sum_{j=1}^{n} a_{i j} x_{j} & =b_{i} \\
\sum_{j=1}^{n} f\left(a_{i j}\right) x_{j}+\left\lfloor a_{i j}\right\rfloor x_{j} & =f\left(b_{i}\right)+\left\lfloor b_{i}\right\rfloor \\
\sum_{j=1}^{n} f \underbrace{f\left(a_{i j}\right) x_{j}}_{\geq 0} & =\underbrace{f\left(b_{i}\right)}_{<1}+\left\lfloor b_{i}\right\rfloor-\sum_{j=1}^{n}\left\lfloor a_{i j}\right\rfloor x_{j}  \tag{4.1}\\
\sum_{j=1}^{n} f\left(a_{i j}\right) x_{j} & \geq f\left(b_{i}\right)
\end{align*}
$$

The last inequality follows from $\left\lfloor b_{i}\right\rfloor-\sum_{j=1}^{n}\left\lfloor a_{i j}\right\rfloor x_{j} \geq 0$. This approach can not only be applied to all rows but to all weighted combinations of rows, especially using any row of the inverse of the current optimal basis matrix $B$ as weights:

$$
\begin{aligned}
\mathrm{B}^{-1} \mathrm{Ax} & =\mathrm{B}^{-1} \mathrm{~b} \\
x_{\mathcal{B}}+\mathrm{B}^{-1} \mathrm{~A}_{\mathcal{N}} x_{\mathcal{N}} & =\mathrm{B}^{-1} \mathrm{~b}
\end{aligned}
$$

Hence, for an optimal solution $\check{x}$ to any LP relaxation with fractional integer variable $x_{i}$, we can construct a Gomory cut based on the corresponding basic row:

$$
\sum_{j \in \mathcal{N}} f\left(\mathrm{~B}^{-1} \mathrm{~A}_{\mathcal{N}}\right)_{\mathrm{i} .} \mathrm{x}_{\mathrm{j}} \geq f\left(\mathrm{~B}^{-1} \mathrm{~b}_{\mathrm{i}}\right)=f\left(\check{\mathrm{x}}_{\mathrm{i}}\right)
$$

With $0<f\left(\check{x}_{i}\right)<1$ and the non-basic variables $\check{x}_{\mathcal{N}}=0$, we can see that the LP solution $\check{x}$ violates the cut since the left-hand side of the inequality is 0 .
These cuts are also called basis-dependent and a similar approach is also possible for MILPs. The resulting inequalities are then known as Gomory mixed-integer cuts. Consequently, SCIP's LP interface needs to provide functionality to get these vectors based on the current optimal basis and every newly generated cutting plane requires the solution of one linear system of equations and the corresponding multiplication with the constraint matrix. This observation also implies that an accurate solution to this system of equations is necessary to avoid computing incorrect cutting planes that may even cut off integer feasible solutions.
Interestingly, we can also use sub-optimal bases to generate such cutting planes as shown by Conforti, Cornuéjols, and Zambelli (2014). During the optimization procedure of the dual simplex algorithm, we compute one row of the form $\hat{\mathfrak{a}}_{p}^{\top}=e_{p}^{\top} B^{-1} A_{\mathcal{N}}$ in every single iteration so it just needs to be stored for later use. After completing the simplex optimization, we can then generate Gomory cuts from those rows without having to compute additional weights. There are even cases where such inequalities from dual feasible bases lead to a tighter LP relaxation than with regular Gomory cuts generated from the optimal basis.

Unfortunately, we have not been able to develop this idea beyond a prototype implementation and could not integrate this approach into the full cut generation and

Figure 4.7.: Visualization of the cutting procedure with the MILP imposed by intersection of the blue region and the orange integrality conditions. LP solution $\check{x}$ on the left is cut off by adding a new valid inequality (red) to better approach the convex hull of feasible points and thereby provide a new relaxation solution $\check{x}_{\text {cut }}$.
filtering system of SCIP. It was unclear how to collect only the interesting data from the LP solver without incurring a prohibitively high computational cost.
There are also combinatorial or other structure-dependent cutting plane methods that do not rely on the simplex basis when generating new valid inequalities. The subtour elimination constraints for solving the traveling salesman problem (TSP) are a popular example. These cuts invalidate the current solution of the relaxed TSP by explicitly forbidding a specific subtour in that solution to force the solver in the subsequent iterations to find a different solution. As there are exponentially many possible subtours, it is not feasible to include them into the formulation directly. Maher, Miltenberger, et al. (2016) demonstrate how such a TSP-solving algorithm can be implemented using PYSCIPOPT.

Interestingly, cutting plane methods can be used exclusively to solve MILPs as discussed by Zanette, Fischetti, and Balas (2011). Manfred Padberg (see Grötschel, 2004 for a portrait of his work) is even credited with stating "branching is a sign of mathematical defeat" (Koch, Martin, and Pfetsch, 2013), essentially elevating cutting over branching. But cutting planes work best when used in combination with the aforementioned branch-and-bound scheme, because they complement each other, typically providing better performance than each approach individually. The details of this synergy are well explained by Basu et al. (2022).
The application of several cutting planes in one round instead of separating them one-by-one was a ground-breaking finding concerning the practical impact of cuts in general.
One obvious disadvantage of adding cutting planes to a problem is that the size of rows increases, making each new LP relaxation slightly more difficult to solve. Furthermore, adding lots of cutting planes also introduces the risk of getting more numerical
instabilities or even losing integer feasible solutions to inaccurate cutting.
SCIP implements various techniques to filter cutting planes before adding them to the LP. For example, sparse cuts, that is, cuts with few non-zero coefficients are preferred. Then, subsequent cutting planes are required to not be too parallel to the already added rows to avoid numerical issues like singular or near-singular basis matrices. Another filtering step limits the allowed range of cut coefficients.

Finally, SCIP also implements a row aging mechanism that tracks for how long a certain cutting plane has been included in the LP without being active or tight at the optimal basis. As soon as a certain age limit has been reached, the corresponding cut is removed from the LP again as it appears to be redundant and does not help tighten the LP relaxation further.

Please note that this is just a rough and incomplete description of the cutting and separation techniques used in SCIP and meant to provide a minimal understanding of the general procedure.

### 4.6. Conflict Analysis

Conflict analysis is the tool to learn from infeasible nodes in the branch-and-bound tree. Infeasibility can result from a branching decision that led to an infeasible LP relaxation in one of the child nodes or from a not improving one with respect to the current best incumbent-a so-called objective cutoff. This objective cutoff can be thought of as additional constraint, hence rendering the LP relaxation infeasible once more.

These infeasible LPs generate a proof of infeasibility in the dual space. This dual ray can be used to derive useful information on the variable bounds to further shrink the feasible domain and reduce the solution space.
There are multiple ways to learn from infeasibility and a good introduction on the topic is presented in Witzig, Berthold, and Heinz, 2019.
Arguably the most involved technique is to add so-called conflict constraints to the LP relaxation. These are additional constraints that encode a specific root cause for infeasibility and learning a good set of conflicts often provides an effective way of improving the quality of the LP relaxations-similar to how cutting planes work.

From the experimental data shown in Figure 4.5, we can see that the time spent in conflict analysis LPs is negligible for almost all instances in our test set.

### 4.7. Primal Heuristics

One of the key components that allow MILP solvers to find optimal or at least very good solutions to $\mathcal{N} \mathcal{P}$-hard problem instances is the clever use of heuristics. We established in Algorithm 1.3 that primal solutions can be found by branching on a variable and discovering that the resulting LP relaxation has an integer feasible solution. In reality, many solutions are found by heuristics to push the primal bound down in a shorter amount of time. The most helpful ingredients in that process are the LP
solutions that can provide a starting point or target for the heuristic. We typically distinguish heuristics into two parts: those that require an integer feasible initial solution and those that do not. Even the former group of improvement heuristics draw on available LP solutions to guide their search.
We are not discussing primal heuristics in detail and rather refer to Berthold (2014) for a comprehensive overview of the topic. We feel that we cannot completely omit these techniques as they usually make up a significant portion of any competitive MILP solver's code base. This is also visible in the chart of SCIP's components in Figure 4.1.

### 4.8. Visualization of MILP Search Trees

Despite the frequent application of MILP models for real world problems, visualizing the actual solving procedure is not straight forward. This can be useful for understanding the process and detecting possible bottlenecks or peculiarities of the solver or of a certain problem instance. A common visualization technique for depicting the solving progress is to plot the advancement in dual and primal solution quality over time. For a minimization problem, the dual solution values are going to be continuously increasing while the primal ones often behave in a piecewise constant fashion, decreasing towards the optimal solution value as depicted in Figure 4.8:

Figure 4.8.: Visualization of the MILP solving progress.
Such charts hide the complexity present in the form of the actual branch-and-bound tree that is constructed and traversed during the optimization.
A natural visualization of the branch-and-bound tree is to draw this exact tree, that is, every branching decision leads to two new child nodes until all open nodes are processed. This is a very detailed way to present the solution process and is well suited to show among other things how balanced a search tree is.
Still, there is room for improvement as the distance between the nodes does not represent the actual distance with respect to the model data. One of the defining
aspects of a node is its LP relaxation and the corresponding LP solution. This is the foundation for a visualization technique that tries to preserve the spatial dimension when drawing the tree. Every LP solution has to be mapped to a two-dimensional point, while maintaining distance in the original space as well as possible. Such a projection can be achieved in several ways. In the following, we use the two techniques multi-dimensional scaling (MDS) and $t$-distributed stochastic neighborhood embedding ( t -SNE) to create a new perspective on MILP search trees. We refer to Kruskal (1964) and Borg and Groenen (2005) for more information on MDS and to Van der Maaten and Hinton (2008) for details on the t-SNE method.

In Figure 4.9 we demonstrate how this transformation works by projecting a simple two-dimensional point cloud onto a line-a one-dimensional space. While it is impossible even for such a simple and low-dimensional example to keep all distances intact, the overall structure-like the two clusters-can be preserved by the transformation.

Figure 4.9:: MDS transformation of a cloud of random points from the two-dimensional plane onto a one-dimensional space. The right image shows the introduced error between pairwise distances of points in the original and the transformed space.

To get a feeling for the quality of distance preservation, a so-called Shepard plot (Shepard, 1962) can be used. This is a simple scatter plot comparing the original with the projected distances for every single pair of points-in our case the individual node LP solutions.

In Figure 4.10 we see a visualization of the MDS-transformed LP solutions of the branch-and-cut tree generated while solving the MIPLIB3 instance lseu. Such threedimensional plots have the tendency to be quite hard to read in print, so we encourage

Figure 4.10.: TreeD visualization of MIPLIB3 instance lseu (89 binary variables, 28 constraints)
the reader to run their own experiments with the TreeD ${ }^{3}$ code and inspect the interactive visualizations themselves. The module can be installed via the standard Python package repository PyPI using the following command:

```
$> pip install treed
```

The main dependencies are PySCIPOPT and hence also the SCIP Optimization Suite to provide all the LP data during the solving process. The transformation of LP solutions is carried out with the help of the Python module Scikit-learn (Pedregosa et al., 2011). In Chapter 6, we show a different use of TreeD that does not produce instance-wise visualizations but collects various LP solving data in a convenient form as pandas DataFrame for subsequent analysis.
The corresponding Shepard plot is shown in Figure 4.11 together with a histogram depicting the distribution of absolute errors in the transformed distances. We can see that despite the stronger reduction in dimensionality, most distances are still preserved reasonably well. Note that instance lseu has 89 binary variables and is solved in 61 nodes.
Apart from the data exploration functionality of Treed, we believe that the generated visualizations also provide a certain artistic value to the field of MILP solving.
We refrain from listing the exact tabular data that was used to generate these plots because of the incurred randomization during the MDS transformation performed in TreeD and the very limited additional value.

[^20]

Figure 4.11.: Shepard plot of original and transformed pairwise distances of all encountered node LP solutions after applying the MDS transformation as seen in Figure 4.10. The absolute errors between the distances are color-coded as seen in the legend. The histogram on the right-hand side provides another view on the same data, revealing that most transformation errors are well below 1.

| settings | iterations | nodes | time | timeout | optimal |
| :--- | :--- | :--- | :--- | :--- | :--- |
| default |  |  |  |  |  |
| no bound flips | 126613.7 | 1686.6 | 124.9 | 51.75 | 123.00 |
| no persistent scaling | 147477.1 | 1668.2 | 122.4 | 51.25 | 120.75 |
| no sparse pricing | 126936.9 | 1792.2 | 137.1 | 55.75 | 114.50 |
| no stable sum | 131192.6 | 1736.3 | 126.0 | 51.00 | 122.50 |

Table 4.2.: Impact of selected SoPLex features on the MIPLIB 2017 benchmark instances. The numbers for iterations, nodes, and time refer to those 96 instances that have been solved to optimality by all solver variants. Columns timeout and optimal show the average number of instances that exceeded the time limit of one hour or could be solved to optimality, respectively. Experiments have been repeated with four different random seeds.

### 4.9. Computational Study

Now that we have established an understanding of the fundamental influence of LP solutions and their solution values throughout the solving process, we want to compare and investigate how changing the specific LP solver impacts the performance of the MILP solver and alters the path to optimality.
First, to see how SCIP performs when deactivating certain features in SoPlex, we use the MIPLIB 2017 benchmark of 240 instances. Every experiment has been performed with four different random seeds to get reliable numbers. The results for SCIP 6.0.2 are shown in Table 4.2. Just as expected from the LP experiments in Chapter 3, we see that without the bound flipping ratio test, more iterations are necessary to solve the instances and we even fail to solve two to three instances within the time limit of one hour. Disabling sparse pricing has barely any impact on SCIP's performance, while persistent scaling clearly helps to solve more instances in less time, fewer nodes, and considerably fewer iterations. The stable sum implementation in SoPlex also has a measurable effect by reducing the number of nodes and simplex iterations and helps to increase the number of solved instances. Note that we are using the shifted geometric mean to compute the average values with a shift of 100 for iterations and nodes and a shift of 1 for the solving time. Timeouts and instances solved to optimality are compared using the arithmetic mean over the four seeded runs.
There is no reasonable way of swapping out the used LP solver without impacting the behavior of the MILP solver. Even if we kept a single, fixed search tree with all the associated node relaxations and starting bases, we could not get a sound comparison of LP solving performance because we would neglect hot-starting effects: restarting the LP solver from just the current basis without a ready-to-use factorization and other internal data structures. This is the reason for not pursuing this approach and rather comparing LP solvers within their respective SCIP LP interfaces. This is a more realistic
take and enables our results to be reproduced without excessive code modifications.
Maher, Ralphs, and Shinano (2019) suggest an interesting visualization technique to compare performance across problem instances that are solved within the given time limit as well as instances that can only be solved to some non-zero optimality gap. Usually, these two sets of instances are separated or the analysis only focuses on those instances that could be solved to optimality by every solver or setting.
This cumulative performance comparison has first been proposed by Dinh, Fukasawa, and Luedtke (2018). In Figure 4.12, we see an example of such a plot comparing the performance of different LP solvers in SCIP on the MIPLIB 2017 benchmark.
We also prefer this combined way of visualizing benchmark results over the traditional performance profiles because the results are presented in a very intuitive way without neglecting suboptimal results. Furthermore, performance profiles can be misleading and are generally harder to interpret as demonstrated by Gould and Scott (2016).

Figure 4.12.: Overall performance comparison of different LP solvers used in SCIP 6.0.2 with default settings solving the MIPLIB 2017 benchmark test set. The horizontal axis is split up into two parts to depict the number of solved instances within the time limit of one hour and the final gap of the remaining instances.

We can see a clear trend of CLP and MOSEK being outperformed by all other solvers, while GUROBI solves the most instances within the time limit and SoPlex being a close runner-up to the three commercial solvers CPLEX, GURObI, and XPRESS.

On the other hand, when comparing the pure LP performance of those solvers, we

|  | shifted geometric mean solving time |  |  |  |  |
| :--- | ---: | ---: | ---: | ---: | ---: |
|  | 1365 instances, all optimal |  | 128 instances, min 5 sec |  |  |
| SCIP settings | default | presoloff |  | default | presoloff |
| LP solver |  |  |  |  |  |
| Gurobi 8.1.0 | 0.980 | 0.800 |  | 49.100 | 39.372 |
| CPLEX 12.8.0.0 | 1.026 | 0.866 |  | 49.814 | 41.954 |
| Xpress 33.01.09 | 1.155 | 1.111 |  | 68.037 | 70.770 |
| MOSEK 8.1.0.21 | 1.327 | 1.172 |  | 96.868 | 85.126 |
| Clp 1.16.11 | 1.411 | 1.460 |  | 101.645 | 112.102 |
| SoPlex 4.0.2 | 1.564 | 1.691 |  | 123.616 | 150.762 |

Table 4.3.: Comparison of different LP solvers in SCIP 6.0.2 on the allLP test set for two settings: default and without SCIP's presolving, each with two random seeds. Times are computed as shifted geometric means (shift of one second) over two sets of instances: those solved to optimality and those that need at least five seconds to be solved.
can observe a different ranking as shown in Table 4.3
These results are also aligned with the LP and MILP benchmark results of Hans Mittelmann ${ }^{4}$ that we will discuss further in Appendix A. Note that we used a modified SCIP code to ignore all integrality information and treat all models as LPs. Please refer to Table B. 1 for the detailed results.

In the following, we want to investigate why SoPLex performs so well when solving MILPs, despite its significantly worse pure LP performance.

Iteration count. When comparing the iteration counts of SoPLex with those of the other solvers, we often observe significantly higher numbers. Take for example problem instance 10teams: SCIP with SoPLEX needs between 7019 and 8033 iterations while all other LP interfaces show an iteration count between 911 and 1730.

Further experiments reveal that-at least for this specific model instance-this is due to the pricing method being used. By default, SCIP uses the LP solver's preferred pricing rule and for most solvers that is a variant of steepest edge pricing. SoPlex, on the other hand, uses its automatic pricing scheme described in Chapter 3 that starts off with devex and then switches over to steepest edge after 10000 iterations. When using the steepest edge pricing rule to solve this instance, SoPLex takes between 1260 and 1550 iterations to find the optimal LP solution-so this is well within the range of the other solvers.
Naturally, the question arises, why this is not the default pricing scheme and computing the shifted geometric mean over all solving times and seeds exposes the rea-

[^21]son: For the test set of all instances solved to optimality the time increases to 1.814 whereas for the harder instances that take at least five seconds for any solver we get an aggregated result of 117.815 seconds. So, while on the second set, there is a slight speed-up, we can observe a slow-down on the first benchmark. This experiment shows that it is not sufficient to judge the LP performance based on the number of simplex iterations alone.

In Figure 4.13, we can see that the times for the different LP solvers to solve the root LPs of the MIPLIB 2017 benchmark instances is less varied than the number of simplex iterations necessary.

Figure 4.13.: Distribution of solving time and iteration ratios for different LP solvers in SCIP to solve the root LPs of the MIPLIB 2017 benchmark instances

Model size and difficulty. Table 4.3 also reveals that SoPlex struggles more with harder instances. There is a factor of about 1.6 between Gurobi and SoPlex regarding the shifted geometric mean time of all instances solved within the time limit. That factor grows to 2.5 for those instances that take more than five seconds for any solver. Furthermore, we can also see that SoPlex (and Clp for that matter) is affected differently by SCIP's presolving: while the faster solvers Gurobi, CPLEX, and MOSEK (XPRESS is barely affected here) are actually able to achieve better times without SCIP presolving the instances, the performance of SoPLEx and also CLP deteriorates. Since the primary goal of presolving is to make an instance more compact, we can accredit this
slowdown to the larger model sizes that the LP solver has to handle when using the presoloff setting.
In practice, hard LPs are often larger than hard MILPs, so it is more likely to see SoPLEX struggle on its own than within SCIP when confronted with such a hard problem instance.

LP iterations and solving times in the tree. As we have established and discussed before, the node LP relaxations are significantly easier to solve, due to to the available warm-start information from a previously processed node. From Figure 4.14, we can deduce that both SoPLEX and CLP require more time and iterations to solve the node LPs relative to the root. What is arguably most surprising here, is that at about depth 30 , the numbers are increasing for those two solvers. Concerning the other four commercial solvers, we see that those relative numbers are clearly smaller leading to a better node throughput as we also confirm in Figure 4.16. And for LPs further down the tree, we can even observe a slight decrease, especially regarding the iteration counts.

Gap closed after the root node. The gap between current dual bound $x_{\text {dual }}$ and incumbent value $x_{\text {primal }}$ is a good measure for progress in an MILP solver. Hence, we want to compare how the choice of a specific LP solver affects the gap closed after the root node. It is important to note that we are using the gap definition of SCIP that differs from those of other solvers like Gurobi and CPLEX. While the latter ones compute the gap as

$$
\frac{\left|x_{\text {primal }}-x_{\text {dual }}\right|}{\left|x_{\text {primal }}\right|}
$$

SCIP uses the formula

$$
\frac{\left|x_{\text {primal }}-x_{\text {dual }}\right|}{\min \left\{\left|x_{\text {primal }}\right|,\left|x_{\text {dual }}\right|\right\}} .
$$

When both bounds have the same sign, the first gap variant moves between zero and one or $0 \%$ and $100 \%$, whereas the one used by SCIP often exceeds the value of 100\%.

Figure 4.15 shows how the different solvers frequently achieve a worse gap than possible with another solver. The gap is displayed on a logarithmic scale so all those results with a zero gap after the root node had to be slightly increased to appear in the chart. This explains the gap in the beginning of the otherwise rather smooth distribution of the best gap per instance.
Table 4.4 lists how often which LP solver reached the best possible gap using the default settings of SCIP and a node limit of one. We see that SCIP with CPLEX is able to provide the best results with regards to this performance measure.

From this experiment we conclude that the choice of LP solver within SCIP strongly affects already the first stage of the solving process before any branching decisions have to be made. Please refer to Table B. 3 for the full results.

Figure 4.14.: Development of node LP solving times and simplex iterations when going down the tree. The metrics are relative to the respective number in the root LP. We only compare MIPLIB 2017 instances that have been solved within the time limit of one hour by all solvers ( 54 instances).

Node throughput. Another interesting measure for LP performance when solving an MILP is the node throughput. Here, we compute how many nodes can be processed in a given time. We restrict the results to instances that had at least a tree size of 100 with the respective solver. For this experiment we also deactivated both separation and heuristics to generate larger tree sizes-without this modification the results would look similar but less pronounced and would be based on a smaller data set. The enhanced box plot or letter value plot in Figure 4.16 is trying to convey more information about the distribution of the results than a conventional box plot. The central box is identical and represents the median with the central line and the two $25 \%$ quartiles next to it. Additional boxes subdivide the values outside of the typical quartiles to provide a more intuitive understanding of the distribution. For more information

instances sorted by best gap
Figure 4.15.: Comparison of the gap after the root node processing for the different LP solvers. A node limit of one and a time limit of one hour was used on the MIPLIB 2017 benchmark set. The instances are sorted by the smallest gap of all solvers.

Table 4.4.: Number of times the respective LP solver reached the best gap after the root node on the MIPLIB 2017 benchmark instances. The root nodes of 177 instances could be finished by at least one solver within the one hour time limit.

| CPLEX | Clp | Gurobi | MOSEK | SoPlex | Xpress |
| ---: | ---: | ---: | ---: | ---: | ---: |
| 79 | 48 | 53 | 55 | 59 | 51 |

about this visualization, please refer to Hofmann, Wickham, and Kafadar (2017).
We can see from this chart that SCIP's node throughput is significantly reduced when using CLP as the LP solver. There is only little difference between the throughput averages of CPLEX, Gurobi, SoPlex, and XPress, with CPLEX taking the lead. MOSEK takes the second last place in this ranking which confirm our previous findings about their respective performance within SCIP.
The full data set for this experiment can be found in Table B.6.

Figure 4.16.: Comparison of the node throughput for the different LP solvers with a time limit of one hour on the MIPLIB 2017 benchmark set. Cutting plane generation and primal heuristics are deactivated. Results are restricted to instances with a tree size of at least 100 . The number of such instances is given underneath the LP solver name.

## Chapter 5

## LP Solution Polishing

Solutions to linear programs are rarely unique. Instead, due to the presence of dual degeneracy and the use of numerical tolerances, multiple distinct solutions may fulfill the optimality and feasibility conditions. Whenever there is a truly unique LP solution, we can often assume the problem to be of artificial nature or a miniature model.

This is especially true for LP relaxations in MILP solvers and one of the main reasons for their performance variability as observed by Koch, Achterberg, et al. (2011). A logical implication of this is trying to use the additional degree of freedom to improve the stability or the performance of the MILP solver. In this chapter, we describe our approach to realize this idea and a computational evaluation of our implementation.

Figure 5.1.: Visualization of two distinct optimal LP solutions $\check{x}$ and $\hat{x}$, with only $\hat{x}$ being integer feasible. Here, the highlighted constraint is parallel to the objective, resulting in degenerate solutions on this optimal facet. LP solution polishing tries to find solutions with fewer fractional integer variables.

### 5.1. Related Work

Searching for another alternative LP solution on the optimal facet is not a new idea and has been investigated in different ways. For a good introduction to degeneracy in MILP problems, we refer to the works of Gamrath, Berthold, and Salvagnin (2020) and Berthold, Gamrath, and Salvagnin (2019) that focus on how branching decisions can be improved by exploiting multiple LP optima. Zanette, Fischetti, and Balas (2011) show how to exploit dual degeneracy by using the lexicographic simplex algorithm to find an optimal basis that is better suited to compute numerically stable cutting planes. A related approach for mixed-integer programming is $k$-sample (Fischetti et al., 2016). This approach runs the initial root LP and the cut loop several times on multiple cores using different random seeds, effectively exploiting the inherent variability. The aim is to collect different LP optima that provide richer cuts for the MILP solver. Alternatively, CPLEX implements an algorithm called pump-reduce (Achterberg, 2013) that fixes several variables and modifies the objective function value to explore different optimal LP solutions to improve cut selection and to reduce the fractionality of the solution.

Please note that there is also a technique called solution polishing by Rothberg (2007) that uses an evolutionary approach to improve upon a given integer feasible solution for MILPs. This is not related to our work-we coincidentally chose a similar name.

### 5.2. Description of the Approach

LP solution polishing tries to improve the quality of an existing LP optimum. The measure of solution quality in this case is the number of integer variables contained in the optimal basis. Since a non-basic variable is always at one of its bounds, it is also integral in the current LP solution because of the integrality of those bounds. Therefore, the fewer basic integer variables are present in an LP solution, the less fractional it can be-typically, a desired feature of solutions within an MILP solver. Of course, basic variables can have integral values as well, but this is less common and happens just by chance, due to their values being determined by the solution of a linear system with the optimal basis matrix, see Algorithm 1.2.

LP solution polishing, as described in Algorithm 5.1, starts after an optimal LP solution is found. The primal simplex method is employed to preserve feasibility of the solution while the pricing step is modified to only look for non-basic continuous variables or slack variables with zero reduced costs or dual multipliers to not deteriorate the objective function value. Then, a modified ratio test only accepts the pivot candidate to leave the basis if it is an integer variable. Otherwise, no basis change is performed. That way, in every successful iteration, the number of integer variables in the basis can be reduced by one.

Initially, the integrality information needs to be communicated from SCIP to SoPLEX to avoid pivoting continuous variables out of the basis and thereby not reducing the

## fractionality.

In contrast to the method described in Achterberg (2013), the presented algorithm does not modify the problem data internally. Furthermore, it is also possible to polish the solution of a pure linear program by treating all variables as integer variables. In general, we consider a polished solution to be superior, because more variables are precisely on their bounds rather than on some arbitrary value within the respective feasibility range.

```
Algorithm 5.1 LP solution polishing in SoPLEX
Input: Optimal solution \(x, y, d\) with basis \(\mathcal{B}\) of LP (1.2)
    \(\mathcal{C}=\{1, \ldots, n\}\)
    \(\mathcal{R}=\{1, \ldots, m\} \quad\) // set of slack variable indices
    \(\mathcal{N}=(\mathcal{R} \cup \mathcal{C}) \backslash \mathcal{B} \quad / /\) set of non-basic indices
    \(\mathcal{I} \subseteq \mathcal{C} \quad / /\) set of integer variable indices
    \(\mathcal{P} \leftarrow \mathcal{N} \cap(\mathcal{R} \cup(\mathcal{C} \backslash \mathcal{I})) \quad / /\) list of non-basic slack or continuous variables
    while \(\mathcal{P} \neq \varnothing\) do
        for \(\mathfrak{i} \in \mathcal{P}\) do // find entering candidate among non-basic indices
            if \(\left(c-A^{\top} y\right)_{i}=0\) then \(\quad / /\) reduced cost or dual multiplier of 0
                select \(\mathfrak{j} \in \mathcal{B} \quad / /\) primal ratio test
                if \(\mathfrak{j} \in \mathcal{I}\) then // found integer variable \(x_{j}\) to leave the basis
                    \(\mathcal{B} \leftarrow \mathcal{B} \backslash\{j\} \cup\{i\} \quad / /\) perform regular basis update
                    \(\mathcal{N} \leftarrow \mathcal{N} \backslash\{i\} \cup\{j\}\)
                    update \(x\) and \(y\)
                    \(\mathcal{P} \leftarrow \mathcal{P} \backslash\{i\} \quad / /\) remove \(i\) from candidate list
                    else
                    no suitable index found to leave the basis, reject candidate \(i\)
                    end if
                end if
        end for
        if no pivot performed or iteration limit reached then
            break
        end if
    end while
    Return: polished solution \(x, y, d\) and basis \(\mathcal{B}\)
```

It has to be considered that the algorithm as it is presented here, does not compute the least fractional LP solution but instead represents a greedy approach. Furthermore, as outlined in Algorithm 5.1, we keep a candidate list of non-basic slack and non-basic continuous variables to speed up the outer selection loop that replaces the pricing step of the simplex algorithm. Degenerate candidates that had to be skipped in a previous round are then tried again for a successful pivot with the updated basis. We employ a small tolerance when checking the reduced costs for degeneracy since these values are rarely exactly zero due to inaccuracies in their computation. The pro-
cedure is terminated when no more successful pivots could be made, the candidate list is exhausted, or the maximum number of iterations has been reached.

### 5.3. Impact on Numerical Stability

We want to investigate how our method influences the numerical features of the final optimal basis. LP solution polishing has the potential to improve the condition numbers of these bases: Pivoting more slack variables into the basis increases the number of unit vectors in the matrix and should result in a smaller condition number (see Chapter 6 for more details on the condition number and numerics in LPs and MILPs).

On the other hand, we can also construct matrices with orthogonal columns-the numerically most stable form with the smallest possible condition number of 1 -and have some of them be almost parallel to a unit vector:

$$
A_{1}=\left[\begin{array}{ccc}
-\epsilon / \alpha & 1 / \alpha & 0 \\
1 / \alpha & \epsilon / \alpha & 0 \\
0 & 0 & 1
\end{array}\right] \text {, with } \alpha=\sqrt{1+\epsilon^{2}}, \quad \kappa\left(A_{1}\right)=1
$$

Swapping the first column of $A_{1}$ for such a unit vector deteriorates the condition number as the columns are not orthogonal anymore and the new matrix $A_{2}$ can be arbitrarily close to singularity:

$$
A_{2}=\left[\begin{array}{ccc}
1 & 1 / \alpha & 0 \\
0 & \epsilon / \alpha & 0 \\
0 & 0 & 1
\end{array}\right], \text { with } \alpha=\sqrt{1+\epsilon^{2}}, \quad \kappa\left(A_{2}\right) \approx 1 / \epsilon
$$

Our experiments on pure LPs from the allLP test set do not show a trend towards improved final condition numbers. This contradicts our intuition towards lower condition numbers with more unit columns in the basis matrix.
Furthermore, the number of new slack variables introduced into the basis is rather insignificant compared to the matrix dimensions of most instances. We also want to stress that due to the utilization of integrality information, we do not necessarily increase the number of slacks in the basis but may also pivot in some continuous variables.

Besides, we know from our experimental results in Figure 6.3 that the condition numbers in the simplex algorithm are very stable as the method iterates toward optimality so we should not expect the additional LP solution polishing to have a strong effect.

Still, we want to present our findings in this area:
Figure 5.2 displays the differences of (logarithms of) the condition numbers of the optimal basis matrices with and without polishing applied to the first LP relaxation. The difference of logarithms relates to the original values $a$ and $b$ as follows:

$$
\log a-\log b=c \Leftrightarrow a=10^{c} \cdot b
$$

Figure 5.2.: Effect of LP solution polishing on the condition numbers of the optimal basis matrix of first LP relaxations of the MIPLIB 2017 benchmark instances. Condition number changes are differences in log10 between a run with and one without enabling polishing.

There is not a single instance exhibiting a change that exceeds more than one order of magnitude and hence we shall not draw any conclusions about the numerical effect of LP solution polishing here. At first glance, there is a trend of increasing condition numbers but this is too small to have any significance. Especially, if we recall that the condition number represents just an upper bound on the input error amplification.
Another metric concerning numerics is the following: SCIP counts the number of unstable LP solves, that is, the number of LP solutions that did not pass the feasibility or optimality check and triggered a fresh LP solve with different parameters. It turned out, though, that in the MIPLIB 2017 benchmark set, there are too few instances that exhibit these unstable solves (only nine across the different polishing settings and seeds) to make any sound conclusion about whether LP solution polishing can help in reducing this number. There were also no noticeable improvements when spot testing on instances that are numerically more challenging.

### 5.4. Reduced Costs on the Optimal Facet

Here, we want to mention another use-case for LP solution polishing with an entirely different goal. Instead of trying to reduce the integrality of a relaxation solution, we want to learn more diverse reduced cost values. In line with the definition of a basis (see Definition 1), only non-basic (slack or structural) variables can have non-zero
dual multipliers or reduced costs. By performing additional simplex steps along the optimal facet we are able to collect a wider range of reduced costs as more variables can be made non-basic. This is only possible in the state of degeneracy, that is when further iterations can be performed without losing optimality of the solution.

The reduced cost values of the current LP solution are used in various places in SCIP. A popular technique is reduced cost strengthening (Nemhauser and Wolsey, 1988; Achterberg, 2009).

### 5.4.1. Reduced Cost Strengthening

Let $\mathcal{B}$ be a basis of an LP in equality form:

$$
\begin{align*}
\min & c^{\top} x \\
\text { s.t. } & A x=b  \tag{5.1}\\
& x \geq 0
\end{align*}
$$

Then, using $B=A_{\mathcal{B}}$ and $N=A_{\mathcal{N}}$, this LP is equivalent to

$$
\begin{align*}
\min & c_{\mathcal{B}} B^{-1} b+\left(c_{\mathcal{N}}-c_{\mathcal{B}} B^{-1} N\right) x_{\mathcal{N}} \\
\text { s.t. } & x_{\mathcal{B}}=B^{-1} b-B^{-1} N x_{\mathcal{N}}  \tag{5.2}\\
& x_{\mathcal{B}}, x_{\mathcal{N}} \geq 0 .
\end{align*}
$$

As we have already established earlier, when the basic variables $x_{\mathcal{B}}=B^{-1} b \geq 0$ and the reduced costs $d_{\mathcal{N}}=c_{\mathcal{N}}-c_{\mathcal{B}} B^{-1} N \geq 0$, then $z_{\text {LP }}=c_{\mathcal{B}} B^{-1} b$ is the optimal value of LP 5.1 and $\mathcal{B}$ an optimal basis-recall that both $\mathrm{d}_{\mathcal{B}}=0$ and $x_{\mathcal{N}}=0$.

Now, assume that LP 5.1 is the relaxation of an IP, that is, all variables are required to be integer $\left(x \in \mathbb{N}^{n}\right)$. Given an upper bound $\hat{z}$ of this IP, we know that an optimal IP solution $\hat{x}$ must satisfy

$$
\begin{equation*}
z_{\mathrm{LP}}+\mathrm{d}_{\mathcal{N}} \hat{\mathrm{x}}_{\mathcal{N}} \leq \hat{z} \tag{5.3}
\end{equation*}
$$

because of the equality

$$
\left\{\min ^{c^{\top} x} \mid A x=b, x \in \mathbb{N}^{n}\right\}=\left\{\min z_{\mathrm{LP}}+\mathrm{d}_{\mathcal{N}} x_{\mathcal{N}} \mid A x=\mathrm{b}, x \in \mathbb{N}^{n}\right\} .
$$

Due to the lower bounds of $x_{\mathcal{N}} \geq 0$ and $d_{\mathcal{N}} \geq 0$, when propagating the previous inequality 5.3 we obtain

$$
x_{j} \leq \frac{\hat{z}-z_{L P}}{d_{j}}
$$

 tighter variable bounds.

Note that if we obtain another optimal basis $\mathcal{B}^{\prime}$, with different reduced costs $\mathrm{d}^{\prime}$, the propagation of variable $x_{j}$ if $d_{j}^{\prime}>0$ is

$$
x_{j} \leq \frac{\hat{z}-z_{\mathrm{LP}}}{\mathrm{~d}_{\mathrm{j}}^{\prime}} .
$$

In fact, we just need to store the largest reduced costs for each variable and use that value to apply the bound strengthening technique.
We implemented a prototype to collect the largest reduced costs during the solution polishing process and use them in SCIP but our experiments have been inconclusive and did not show a significant enough performance improvement to justify the additional overhead of maintaining the modified reduced cost storage. Still, we believe that there is some hidden potential here that should be investigated further.

### 5.4.2. Cutting Plane Evaluation

Another application area for reduced costs in an MILP solver is during the cut filtering process. A cutting plane that has non-zero coefficients for variables with positive reduced costs is expected to result in an improved dual bound in the next LP solution. Hence, more diverse reduced costs may enable a more reasonable cut selection. This idea has first been presented by Achterberg ${ }^{1}$ and is described in the patent by Achterberg (2013). We did not test this extension in our implementation.

### 5.5. Computational Study

Since the choice of a different LP basis can drastically alter the solution path of SCIP, we need to carefully separate random effects from actual influences of our algorithm.
While the procedure is not supposed to change the objective function value, it may still happen in rare cases-especially when dealing with numerically sensitive models.
In Figure 5.3, we demonstrate the effect of LP solution polishing on the very first LP that is solved for each of the MIPLIB 2017 benchmark instances. We can see that for about half of the instances, there is a reduction in the number of fractional integer variables in that first LP solution and there are several instances with a drastic fractionality reduction of up to $80 \%$. The additional simplex iterations incurred by the polishing procedure correspond to that reduction: For those instances that do not benefit from our technique, there is also barely any overhead-with a few exceptions. The iteration increase is at most about $40 \%$ and often a lot less. The extra time required to perform those polishing iterations displays a more erratic behavior: The largest increase is almost $80 \%$ but only nine instances require $20 \%$ or more additional solving time. The majority of samples remains well below $10 \%$ time increase. Note that we used averages from three different random seeds running with and without polishing in the root node. For the full data behind this chart, please refer to Table B.2.

Evaluating the effect of LP solution polishing on the overall performance of SCIP reveals a positive impact. Here, we compare four different settings: polishing for all LPs, polishing only for the root LP, polishing disabled, and the default mode. This default mode activates LP solution polishing during the probing and diving stages of

[^22]

Figure 5.3.: Effect of solution polishing on the fractionality of the first LP solution for the MIPLIB 2017 benchmark instances. The green line depicts the relative fractionality reduction while the blue and orange bars show the relative increase in iterations and solving time for that specific instance. We used the averages of three random seeds running with SCIP version 7 .

SCIP. These are used for various purposes in SCIP to initiate a quick LP exploration path where fewer fractional variables are deemed to be very useful. Experiments have revealed that this slightly reduced application of polishing leads to the best performance as also Table 5.1 demonstrates.

We can see from these results that our technique helps to solve three more instances to optimality while reducing the shifted geometric time to optimality by more than $6 \%$. The number of nodes can be reduced by almost $8 \%$ and the primal-dualintegral (Berthold, 2014) for the solved instances is reduced by $3 \%$. The latter measure indicates how quickly the primal and dual bounds move towards each other by computing the integral of the difference of those two numbers over the solving time.

Figure 5.4 overlays the root node fractionality reduction with the speedup factors of the total solving times. We see that instances with a larger speedup due to polishing, that is, instances with a downward-pointing bar, are more often showing a reduced root node fractionality. We can also observe that for instances with no root node fractionality reduction there is a higher chance of a slow-down when using polishing.

| group | settings | count | solved | limit | time |  | nodes |  | PDI |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |

|  | rootpolish | 92 | 92 | 0 | 93.80 | 1.041 | 1815 | 1.057 | 8764.8 | 0.972 |
|  | alwayspolish | 92 | 92 | 0 | 92.84 | 1.030 | 1692 | 0.985 | 9196.5 | 1.020 |

Table 5.1.: Different LP solution polishing settings on the MIPLIB 2017 benchmark instances with SCIP 7, a time limit of one hour, and three random seeds for every setting. Shifted geometric means are computed with a shift of 1 for the time values and a shift of 100 for the node counts. The quotients for respective numbers is always using the default settings as comparison.

### 5.6. Conclusion

This chapter demonstrates how the simplex method can be tweaked to exploit degeneracy in MILP relaxations to provide a better solution with fewer fractional variables. LP solution polishing can strongly reduce the LP fractionality on certain instances, often without considerably increasing the solving time. This has also a positive effect on the overall MILP performance on SCIP helping to solve more instances in a shorter amount of time.

LP solution polishing is not affecting numerical stability in a significant way, neither by observing condition number changes nor by counting the number of unstable LP solves within SCIP. Note that we did not test this on numerically challenging instances but on the MIPLIB 2017 benchmark instances that have rather reasonable numerical features. The following chapter deals with the topic of numerics and explains the concept of stability and condition numbers.

Figure 5.4.: Effect of solution polishing on the total solving time for the MIPLIB 2017 benchmark instances. The green line depicts the relative fractionality reduction while the blue bars show the speedup of using the default polishing mode compared to disabled polishing. The numbers are in log2 scale, so factors below zero indicate a speedup. We used the averages of three random seeds running with SCIP version 7.

## Chapter 6

## Numerics in Branch \& Bound \& Cut

Whenever we are dealing with numerical computations we need to be aware of inaccuracies that can be related to the problem to solve, the data that comprise the problem, and the specific algorithm employed.

Let us open the discussion with an extreme example: Due to the necessary use of numerical tolerances, it may happen that an ill-posed problem can be correctly regarded as both feasible and infeasible. An analogy outside of the mathematical context is the image presented in Figure 6.1 that can be read as two very different words:

Figure 6.1.: Calligraphic illusion "Laurel \& Yanny". Image credit: https://twitter . com/AriadneRem/status/996609946228703232

A corresponding LP example is the following feasibility problem:

$$
\begin{align*}
x+10^{-8} \cdot y & =10^{-7}  \tag{6.1}\\
x, y & =0 .
\end{align*}
$$

Using the commonly used tolerance of $\epsilon=10^{-6}$, there clearly are feasible solutions to this mathematically infeasible problem: Consider $x$ to be basic, the non-basic variable $y$ is then set to zero. This results in the numerically tolerated solution of $(x, y)=\left(10^{-7}, 0\right)$. For $y$ basic, though, the simplex method cannot find a solution and reports infeasibility because with non-basic variable $x$ set to zero, $y$ has to be 10 , strongly exceeding its bound regardless of the tolerance $\epsilon$. Both results are numerically correct. While this is an artificial example, such inaccuracies are a frequent issue and may lead to serious complications when the precise results are required.

## 6. Numerics in Branch \& Bound \& Cut

Chip design verification-one of the earliest application areas for SCIP as presented by Achterberg (2007)-is a good example of such a problem class.
There have been various attempts to use a "condition number" to assess the numerical difficulty or categorize problem instances. We want to give an overview and comparison on a number of different conditions and measures suitable for MILP solvers. Usually, the field of numerical analysis focuses on continuous problems and we want to transfer these methods and techniques over to the discrete world of mixed-integer linear programming. Furthermore, we focus on the applied component rather than the theoretical part because the traditional ideas of stability and convergence do not fit the discrete nature of MILPs.

First, we need to give a short introduction to the general concepts used in this chapter.

### 6.1. Background on Numerical Analysis

Two terms are frequently used when discussing numerical properties of a problem or an implementation: stability and condition. Stability usually refers to backward stability and measures the deviation between the algorithmically calculated solution to a problem and the true solution to a slightly perturbed problem. This quantity is independent of the data of the problem and is instead a property of the algorithm used to find the solution. Hence, it is also often referred to as stability of an algorithm. Condition on the other hand, is independent of the algorithm and is bound to the input data. For a given problem $f$ with input $x$ it can be defined as

$$
K=\lim _{\epsilon \rightarrow 0} \sup _{\operatorname{err}_{\mathrm{rel}}(x) \leq \epsilon} \frac{\operatorname{err}_{\mathrm{rel}}(f(x))}{\operatorname{err}_{\mathrm{rel}}(x)}
$$

The relative error is defined as

$$
\operatorname{err}_{\text {rel }}(x)=\frac{\|x-\tilde{x}\|}{\|x\|}
$$

Of course, these definitions are dependent on a certain norm $\|\cdot\|$. Whenever it is not explicitly mentioned, we assume the Euclidean norm $\|\cdot\|_{2}$ for vector spaces.
The condition number к measures how much the input error magnifies the output error when using exact arithmetic. It is important to understand that the stability of an algorithm cannot mitigate a high condition number of the numerical problem statement.
We can formulate this rule of thumb for numerical computations: A stable algorithm for a well-conditioned problem is expected to compute an accurate solution.

Arguably the most important condition number is the one for inverting a square matrix $A$ and is commonly known as the condition number of a matrix that was intro-

[^23]duced by Turing (1948). We also stick to this convention and recall its commonly used computational form:

Definition 4 (Condition number of a matrix). The condition number к of a square matrix $A \in \mathbb{R}^{n, n}$ is defined as

$$
\kappa(A)=\|A\|\left\|A^{-1}\right\| .
$$

This is actually a result of a more fundamental and geometric way of thinking about the condition of a problem using the notion of ill-posedness attributed to Hadamard (1902):

Definition 5 (Ill-posedness). A problem is well-posed if it has a (unique) solution and the solution depends continuously on the input. A problem that is not well-posed is ill-posed.

This definition is kept vague on purpose because the meaning of ill-posedness depends heavily on the actual problem in question.
For the problem of inverting a square matrix, though, the set $\Sigma$ of ill-posed problems consists of all singular matrices. Then the distance to ill-posedness can be defined as

$$
d(A, \Sigma)=\min \{\|A-S\|, S \in \Sigma\} .
$$

Theorem 2. For $A \in \mathbb{R}^{n, n}$ the following holds.

$$
\mathrm{d}(A, \Sigma)=\frac{1}{\left\|A^{-1}\right\|}
$$

Using Definition 4, we can connect the condition number with the distance to illposedness:

$$
\kappa(A)=\frac{\|A\|}{d(A, \Sigma)} .
$$

This allows us to interpret the condition number of matrix $A$ as the inverse of the relative minimum distance to an ill-posed or singular matrix. Depending on the used norm $\|\cdot\|$, there are also techniques for estimating the condition number as shown by (Hager, 1984) for the $\ell_{1}$-norm. Bürgisser and Cucker (2013) provide both an excellent overview and an in-depth analysis of condition numbers and the stability of numerical algorithms.
An illustrative use of condition numbers comes in the form of the stability analysis of an algorithm that is sketched in Figure 6.2. Let $\hat{f}: X \mapsto Y$ be the algorithm to solve a given problem $f$. For any input $x$ the result $\hat{f}(x)$ may differ from the true solution $f(x)$. Yet, there is a $\tilde{x} \in X$ that satisfies $f(\tilde{x})=\hat{f}(x)$. The difference between $x$ and $\tilde{x}$ is called backward error, while the forward error is the difference between $f(x)$ and $\tilde{f}(x)$. The

Figure 6.2.: Forward and backward error
algorithm $\tilde{f}$ is said to be stable or backward stable if the backward error is bounded by the forward error multiplied with the condition number of the problem:

$$
\operatorname{err}_{\text {rel }}(f) \leq \kappa_{f}(x) \cdot \operatorname{err}_{\text {rel }}(x)
$$

There are several studies on the condition number of convex optimization problems, which are generalizations of LP problems. Ordonez and Freund (2003) and Epelman and Freund (2002) measure the condition by looking at the entire problem, including right-hand side and objective function. The main focus of the work of Ordonez and Freund (2003) was to find a correlation between the condition number and the number of iterations an interior point algorithm would need to solve an LP instance.
Another result is that the majority of NETLIB LP instances (see Koch, 2004b for an overview) are actually ill-posed with respect to this condition metric. This is interesting in so far as those instances have been used for decades in benchmarks and publications and are nowadays considered mere toy problems that most solvers can easily deal with. So, we are inclined to find another condition metric that hopefully gains a better understanding of whether an instance is numerically difficult.
Important to note is that Ordonez and Freund (2003) succeeded using their LP condition number to estimate the necessary number of iterations an interior point method would need to solve a given instance. They achieved this by applying industry-standard presolving reductions to the models, before computing the condition number. The presolved NETLIB instances are also mostly well-defined with respect to their condition number. This presolved model then also corresponds to the actual data the solver uses to compute the solution, so there is a stronger relationship compared to using the instances in their original form.
We re-implemented this condition metric and will apply it to MILP instances later in this chapter.

LP condition number Bürgisser and Cucker (2013) extend the definition of condition as distance to ill-posedness to linear programs in the following way:

Definition 6 (LP condition number). For a feasible and well-posed $L P \min \left\{c^{\top} x \mid A x=\right.$ $b, x \geq 0\}$ with optimal basis $\mathcal{B}$ we define the condition number as

$$
\kappa_{L P}(\mathcal{A})_{\mathrm{rs}}:=\frac{\|\mathcal{A}\|_{\mathrm{rs}}}{\mathrm{~d}_{L P}\left(\mathcal{A}, \Sigma_{L P}\right)}
$$

This requires the definition of the distance $d_{\text {LP }}$ of an LP to ill-posedness and also a classification of ill-posed LPs. In line with the above notion we declare every LP illposed, that does not have a unique solution. This also includes all LPs with degenerate optimal solutions. Furthermore, infeasible or unbounded LPs are only ill-posed if they are sufficiently close to an LP that has an optimal solution.
We call this set of ill-posed LPs $\Sigma_{\text {Lp }}$.
Definition 7 (LP distance to ill-posedness). For a feasible and well-posed LP with data $\mathcal{A}$ we define the distance to ill-posedness as

$$
\mathrm{d}_{L P}\left(\mathcal{A}, \Sigma_{L P}\right)=\inf \left\{\|\Delta \mathcal{A}\|, \mathcal{A}+\Delta \mathcal{A} \in \Sigma_{L P}\right\} .
$$

Naturally, this distance is zero for ill-posed LPs. Note that $\mathcal{A}:=\left[\begin{array}{ll}A & b \\ c^{\top} & 0\end{array}\right]$.
For infeasible or unbounded LPs that are not in $\Sigma_{\text {LP }}, d_{\text {LP }}$ is undefined. Just like in Definition 4 for square matrices, we want to have an alternative formulation for the condition number of LPs that is more concrete and computationally tractable. A result from Bürgisser and Cucker (2013) about the distance to ill-posedness delivers the necessary tool:

Theorem 3. For a feasible and well-posed LP with data $\mathcal{A}$ and optimal basis $\mathcal{B}$ the following holds for the distance to ill-posedness:

$$
\mathrm{d}_{L P}\left(\mathcal{A}, \Sigma_{L P}\right)=\min _{S_{\in S_{1} \cup S_{2}}\{\|\Delta \mathrm{~S}\|, \mathrm{S}+\Delta \mathrm{S} \text { is singular }\}}
$$

with

$$
\begin{aligned}
& S_{1}:=\left\{m \times m \text { submatrix of }\left[\begin{array}{ll}
A_{\mathcal{B}} b
\end{array}\right]\right\} \\
& S_{2}:=\left\{m+1 \times m+1 \text { submatrix of }\left[\begin{array}{c}
A \\
c^{\top}
\end{array}\right] \text { containing } A_{\mathcal{B}}\right\} .
\end{aligned}
$$

Applying Theorem 2 allows us to formulate the LP condition number of Definition 6 with respect to those matrix sets:

$$
\operatorname{KLp}(\mathcal{A})_{\mathrm{rs}}=\|\mathcal{A}\|_{\mathrm{rs}} \cdot \max _{S_{\in} \in \mathrm{S}_{1} \cup \mathrm{~S}_{2}}\left\|\mathrm{~S}^{-1}\right\|_{\mathrm{sr}}
$$

with $\mathcal{A}, S_{1}$, and $S_{2}$ as above.
Computing this number is possible but rather expensive: In the set $S_{1} \cup S_{2}$ there are $n+1$ matrices of which we need to calculate the norm of the inverse. Depending on the norm, that is, the choice of $r$ and $s$, it can be computationally tractable.
There are further metrics that can be studied to gain an understanding of the numerical properties of a problem.

Determinant The determinant $\operatorname{det}(A)$ of a square matrix $A \in \mathbb{R}^{n, n}$ is equal to the product of its eigenvalues. Geometrically, it is the volume of the convex hull spanned by the columns of $A$. There are some interesting algebraic properties of the determinant:

$$
\begin{aligned}
\operatorname{det}(I) & =1 \\
\operatorname{det}\left(A^{-1}\right) & =1 / \operatorname{det}(A) \\
\operatorname{det}(c A) & =c^{n} \operatorname{det}(A) \\
\operatorname{det}(A B) & =\operatorname{det}(A) \operatorname{det}(B), \text { for } B \in \mathbb{R}^{n, n} .
\end{aligned}
$$

Furthermore, the determinant of a triangular matrix is the product of its diagonal entries $\Pi a_{i i}$. Together with the above multiplicativity, we can easily compute the determinant of a matrix factorized as LU with lower and upper triangular matrices L and u :

$$
\operatorname{det}(A)=\operatorname{det}(L U)=\operatorname{det}(L) \operatorname{det}(U)=\prod_{i=1}^{n} l_{i i} \prod_{i=1}^{n} u_{i i}
$$

Since the diagonal entries of $L$ are usually set to one, the computation is further simplified to the product of the diagonal elements of U. Additionally, one needs to be aware that due to permutations in the factorization, $\operatorname{det}(A)$ might have a different sign than $\operatorname{det}(\mathrm{U})$, which can be avoided by just regarding the absolute values.

Trefethen and Bau (1997) comment on the determinant: "The determinant, though a convenient notion theoretically, rarely finds a useful role in numerical algorithms". Take for instance the diagonal matrix $A=\operatorname{diag}\left(1^{-3}, \ldots, 1^{-3}\right)$. Its determinant is $\operatorname{det}(A)=$ $1^{-5 n}$ which can be arbitrarily close to zero, indicating closeness to singularity. The corresponding condition number on the other hand is $k(A)=1$, specifying that it is far away from singularity or ill-posedness.

Nevertheless, Zanette, Fischetti, and Balas (2011) investigate how cutting planes affect the determinant of optimal basis matrices. The determinant is also a measure of the size of the matrix coefficients: It is the (signed) volume of the parallelepiped constructed of the columns of the matrix. For their example with stein15-a pure 0/1 problem-it is reasonable that the matrix coefficients grow if cuts are added with coefficients larger than 1 . Also, when using the lexicographic simplex to perform the reoptimizations, the added cuts are less likely to be active and the following cut round is not going to base new cuts on top of them. While it might be worthwhile to investigate determinants in addition to condition numbers for certain problem classes, we could not find a good use of this metric for general LPs or MILPs.

Trace The trace $\operatorname{tr}(A)$ of a square matrix $A \in \mathbb{R}^{n, n}$ is defined as the sum of its diagonal entries $\sum_{i=1}^{n} a_{i j}$. Interestingly, the trace is also the sum of eigenvalues of the matrix:

$$
\operatorname{tr}(A)=\sum \lambda_{i} .
$$

Unfortunately, the trace is not multiplicative, that is $\operatorname{tr}(A B) \neq \operatorname{tr}(A) \cdot \operatorname{tr}(B)$, so we cannot directly compute this metric from the LU factorization. Still, we implemented
the computation of the sum of diagonal elements of $U$ in SoPLex but could not find a useful application for this measure.

As the eigenvalues of a triangular matrix are the elements on its diagonal, we can easily determine the smallest and largest eigenvalues. We use this ratio of diagonal extreme values of $U$ as estimate for the condition number $\kappa$ of $A=L U$.

In total, SoPlex provides the following matrix metrics for the current basis matrix $A_{\mathcal{B}}=\mathrm{LU}$ at every iteration of the simplex algorithm:

- determinant of the basis matrix $A_{\mathcal{B}}$
- trace of $U$ from the current LU factorization $A_{\mathcal{B}}=\mathrm{LU}$
- estimated condition number of $A_{\mathcal{B}}$ by computing the ratio of largest and smallest absolute values of the diagonal elements of $U$

Skeel's condition number Yet another metric one might consider is Skeel's condition number. This is defined as

$$
K_{\text {skeel }}(B)=\left\|\left|B^{-1}\right| \cdot|B|\right\|_{\infty}
$$

and has been proposed by Skeel (1979), although the naming convention followed later by other authors. It differs from the classical condition number $\kappa(B)$ by taking the element-wise absolute values of all matrix coefficients. This results in a condition number that is always less or equal to k and most importantly invariant to row scaling:

$$
B=\left[\begin{array}{cc}
1 & 0 \\
0 & 10^{9}
\end{array}\right], \quad K(A)=10^{9}, \quad K_{\text {skeel }}(B)=1 .
$$

Unfortunately, this variant of the condition number is even more difficult to compute and this is likely the reason for it not being used more often in practice. We did not perform any experiments or analyses with Skeel's condition number but still feel that mentioning it here is justified and may inspire future research.
We investigate and analyze how the numerical features of an MILP instance evolve during the solving process.

### 6.2. Numerical Analysis for LP and MILP

In this section we are going to explore the numerical stability of the branch-and-cut algorithm. There is a strong connection between the geometry of a specific instance and its numerical properties. Unfortunately, it is not known how to visualize or grasp this geometry for any reasonable problem sizes, so various abstractions and approximations are required. One such measure is the condition number of the basis matrix that is used in the simplex algorithm. Recall the definition of the traditional condition number $\kappa$ of a (regular square) matrix $A$ :

$$
\kappa(A):=\|A\| \cdot\left\|A^{-1}\right\| .
$$

Although this number specifies the condition or distance to ill-posedness of solving a linear system of equations, it is still an appropriate measure for several other operations with this matrix or its inverse-especially as we are dealing with many linear systems when solving LPs and MILPs.

Let us inspect some examples to illustrate the expressiveness of the condition number. First, a matrix with a large range of coefficients:

$$
A=\left[\begin{array}{cc}
10^{5} & 1 \\
0 & 10^{-5}
\end{array}\right], A^{-1}=\left[\begin{array}{cc}
10^{-5} & -1 \\
0 & 10^{5}
\end{array}\right] \text { with }\|A\| \approx 10^{5} \text { and }\left\|A^{-1}\right\| \approx 10^{5} .
$$

Hence, for the condition number $k(A) \approx 10^{10}$. We see that mixing coefficients of vastly different magnitudes easily lead to large error amplifications and should be avoided in the modeling phase. Of course, scaling can be used to reduce the range but, as noted before, may then cause an increase of violations in the original space when there are (numerically tolerated) violations in the scaled space.

Next, let us consider a matrix with large coefficients and a reduced range:

$$
A=\left[\begin{array}{cc}
10^{5} & 1 \\
0 & 10^{5}
\end{array}\right], A^{-1}=\left[\begin{array}{cc}
10^{-5} & -10^{-10} \\
0 & 10^{-5}
\end{array}\right] \text { with }\|A\| \approx 10^{5} \text { and }\left\|A^{-1}\right\| \approx 10^{-5} .
$$

Here, the condition number $k(A) \approx 1$ is a lot smaller than the former case and is not going to cause numerical issues-it is very close to a diagonal matrix. Still, those large coefficients can deteriorate violations in the transformed or presolved space depending on the bounds of the variables and right-hand sides of the constraints. Again, despite this case being way less critical than the first example, we should still aim for reducing the overall magnitude of coefficients.

Finally, we want to demonstrate the case of a deceptively well-behaved matrix $A \in$ $\mathbb{R}^{n, n}$ :

$$
A=\left[\begin{array}{ccccc}
1 & -2 & 0 & \ldots & 0 \\
0 & 1 & -2 & \ddots & \vdots \\
\vdots & \ddots & \ddots & \ddots & 0 \\
0 & \ldots & 0 & 1 & -2 \\
0 & \ldots & \ldots & 0 & 1
\end{array}\right], \quad A^{-1}=\left[\begin{array}{ccccc}
1 & 2 & 4 & \ldots & 2^{n-1} \\
0 & 1 & 2 & \ddots & \vdots \\
\vdots & \ddots & \ddots & \ddots & 4 \\
0 & \ldots & 0 & 1 & 2 \\
0 & \ldots & \ldots & 0 & 1
\end{array}\right]
$$

This matrix has a very small range of coefficients, the norm is also very small, but the coefficients of the inverse grow exponentially with the size of the matrix. Such a banded matrix appears in a benchmark set of quadratic programming instances collected by Maros and Mészáros (1999). This laser or ilaser model instance originates from the field of electrical engineering and has caused us some headaches when trying to avoid numerical resonance catastrophes in the solving process; eventually, we concluded that there is no cure for this instance and a warning message alerts the user that the model is likely ill-posed.
A common guideline and recommendation is to inspect the ranges of the coefficients of a problem instance. As the last example shows, this is not sufficient to guard
against all numerical issues. For a more informed analysis, we need to include further metrics like the condition number as proxy for the problem's geometry.
To estimate the condition number of the current basis matrix, we implemented the power method in SoPLex. After repeated multiplication with A followed by a normalization, a randomly chosen vector converges to the largest eigenvector that can be used to get the corresponding eigenvalue. In a similar fashion, we can repeatedly apply $A^{-1}$ to get the smallest eigenvalue. Typically, a few iterations are enough to converge and the computational overhead is relatively small due to the readily available LU-factorization of the basis matrix. Given that the condition number is merely providing a rough upper bound on the expected error when solving a linear system with this matrix, we do not require high accuracy and focus on the magnitude by inspecting the logarithmic value, instead.
We use Treed to collect the condition numbers for all the simplex bases in a SCIP optimization run. Since Treed utilizes the LP event handler of SCIP, it allows easy access to various LP statistics that can then be stored for later analysis. The LP event handler is a callback that is executed whenever an LP is solved and allows capturing the relevant data for this specific LP. In the interactive version of Treed the user is able to choose those metrics to be displayed in the nodes of the tree visualization.

Discussing the condition of a discrete problem is in fact quite complicated. Formally, the slightest deviation of an integer variable from its value in an optimal (or feasible) solution will render the new solution infeasible. This is due to the solution set being an entirely discrete and hence discontinuous set. The classical concept of conditioning on the other side is tailored to continuous or smooth neighborhoods around the data points. Accordingly, we would have to set the condition number to $\infty$ rendering every single integer programming problem ill-conditioned. We refer to the work of Jarck (2020) for a detailed discussion on the topic.

This discrepancy is a stark contrast to the practical applicability of integer programming, so we retreat to inspecting condition numbers originating from LP relaxations of those problems. As large parts of the computational MILP solving process rely on LP solving as we have seen in Chapter 4, we believe that it is reasonable to do so.
Recently, developers of the FICO XPRESS solver presented a "numerical attention" prediction based on machine learning ${ }^{2}$. The attention level $\alpha$, that is estimated using this approach, is defined as follows:

$$
\begin{array}{rlrl}
\alpha & :=0.01 * p_{\text {sus }}+0.3 * p_{\text {unstab }}+p_{\text {ill }} \\
& & \\
& \text { with } &  \tag{6.2}\\
p_{\text {sus }} & :=\text { percent of suspicious LP bases, } & & 10^{7} \leq \kappa<10^{10} \\
p_{\text {unstab }} & :=\text { percent of unstable LP bases, } & & 10^{10} \leq \kappa<10^{14} \\
p_{i l l} & :=\text { percent of ill-posed LP bases, } & & 10^{14} \leq \kappa .
\end{array}
$$

The reasoning behind those classification ranges is explained in Section 6.6 when discussing different data types and how those influence the accuracy of our results.

[^24]This definition has first been published in a patent from IBM for CPLEX3 ${ }^{3}$. The concept of collecting various k values during the MILP solving process is also known as MIPKарра or MIP-к.

Both CPLEX and XPRESS use the same definition of the attention level $\alpha$ and recommend users to be careful as soon as $\alpha>0$. Since computing $\alpha$ can be expensive because many condition numbers need to be computed, a cheaper way of getting an idea of the numerical stability is certainly welcome. Furthermore, $\alpha$ is only available after the optimization has already been finished. The prediction takes into account several readily-available characteristics of the model data like coefficient ranges and bound sizes. Its quality is reportedly good enough to serve as a warning indicator: Models with a problematic $\alpha$ are reliably detected, while false positives, that is, instances that do not turn out to be numerically challenging, might still provoke a warning. Essentially, when the prediction is incorrect, in most cases it provides an unnecessary warning. This is not an issue for real-world applications and operations research practitioners.

### 6.2.1. Conditioning of the Simplex Algorithm

There are elaborate and quite complex definitions of the stability of a linear programming problem-independent of the used solving technique-as described by Bürgisser and Cucker (2013). These take the entire problem instance-including right-hand side and objective function-into account to provide a more general view on its numerical features.
We choose a simpler approach that relies only on the current basis matrix and the corresponding conventional condition number. This provides both a computationally feasible implementation as well as a reliable and expressive assessment of the actual numerical stability.
Figure 6.3 shows the condition number of each basis matrix encountered during the solving process of the initial LP relaxation and during each iteration of the re-solve occurring after adding a new round of cuts for selected instances from our test set.

One can observe that during the early iterations-especially of the initial relaxation in the root node-the condition numbers of the basis matrices grow quickly. This is expected, as more structural variables are pivoted into the basis, while slack variables are pivoted out. As the initial basis is typically the identity matrix which has a condition number of one, the conditioning can only degrade at first. We can conclude that during the simplex algorithm, condition numbers of the basis matrices grow quickly until the characteristic condition number magnitude is reached.
We expect the condition numbers of the basis matrices to degrade further as a result of operations performed in the root node and our initial computations are aimed at confirming this. After the initial optimization, the MILP solver adds cutting planes to the LP that are computed using the current basis matrix itself as explained in Sec-

[^25]

Figure 6.3.: Condition number development (vertical axis, in log scale) for every simplex iteration in the root node (horizontal axis) including re-optimizations after adding cutting planes in multiple rounds (vertical lines). A plot of objective values at each iteration is overlaid as a dashed gray line with the scales given to the right of each plot.

Figure 6.4.: Root node comparison of condition numbers of the original LP and after including cutting planes. Most instances show a higher condition number during the cutting stage and when this process is completed.
tion 4.5. Consequently, an ill-conditioned basis matrix may lead to an imprecise calculation of the coefficients of the new inequality.

Moreover, adding these new rows to the LP often further deteriorates its condition number as can be seen in Figure 6.3. This sample of MIPLIB instances clearly shows the expected behavior.

Figure 6.4 is a visualization of the difference between the condition number of the optimal basis of the original LP and two other metrics: (1) the average over all bases encountered during the cutting procedure and (2) the condition number of the final optimal basis. While for some instances there is a slight improvement after adding cuts, in most cases addition of cuts leads to the expected increased condition number.

Please note that these plots are taken from Miltenberger, Ralphs, and Steffy (2018) with an earlier version of the analysis code.

### 6.2.2. Condition Number Trend in the Tree

When inspecting condition numbers, there can be pretty large differences between individual instances and aggregating those numbers can easily be misleading. We demonstrate this in Figure 6.5 that shows the expected range of condition numbers for a specific tree depth and parameter setting. We use the breadth-first search node selection rule (see Section 4.4) to generate a more balanced tree.
Additionally, we adjust SCIP's separation emphasis parameter to compare runs with disabled cutting plane generation, runs with more aggressive separation, and the default cut setting. One might expect larger condition numbers when more cutting planes are added to the problem and smaller condition numbers when there are no additional cutting planes. However, this is not something we can deduce from this chart. It is apparent that cutting planes contribute to a smaller tree size and that condition numbers appear to decrease for LPs in deeper nodes of the tree.

The latter observation is flawed, though, because the number of instances that reach a certain tree depth is also diminishing accordingly. We are effectively comparing different sets of instances when descending the depth level in this chart.

An alternative might be to use a relative depth measure to normalize the different tree sizes. Unfortunately, this produces even more distorted results and prevents any sensible deduction or conclusions.

We actually need to inspect either individual instances to get a feeling for the condition number development or compute a trend per instance and then investigate similarities.

As we can see from Figures 6.6 and 6.7 , the condition number trend in the branch-and-cut tree can be quite unpredictable and does not necessarily follow the intuitive expectation of more cutting planes implying larger condition numbers.

Figure 6.5.: Aggregated condition numbers (in log10 scale) for different tree depths. This chart contains data for all instances from the different MIPLIB benchmark sets that could be solved in one hour and that have at least reached a tree depth of 10 . The line represents the mean value of condition numbers at this level while the shaded area shows the respective $95 \%$ confidence interval. Compared parameter sets are using breadth-first search with different cutting plane separation strategies (default, aggressive, and off).

### 6.3. Tailing-off Effect of Cutting Planes

The tailing-off effect of cutting planes describes the diminishing dual bound improvement of additional cutting planes during the separation procedure.
While it is possible to reach optimality with cutting planes alone, most solvers rely on further techniques like branching to reach optimality. Zanette, Fischetti, and Balas (2011) discuss this topic in more detail.

One of the main culprits for cuts having less impact over time is the fact that more

Figure 6.6.: Expected developments of condition numbers (in log10 scale): aggressive separation (sepaaggr) leads to an increased condition number across the entire tree while disabled cutting plane separation generates a larger tree but has smaller condition numbers.
cuts of higher rank have to be added and those tend to cause numerical difficulties. The rank of a cut describes whether the cut is coming directly from the LP formulation or is derived from a previous cutting round.

Intuitively, one can imagine this process as slowly shaving off the edges of the polyhedron making it harder for the simplex method to determine an optimal vertex among many very similar sub-optimal ones. Many almost parallel rows in the LP naturally lead to high condition numbers and may induce inaccurate results.

Following this train of thought, we seek to find a correlation between the stagnating bound improvement and an increased condition number of the corresponding basis matrices. In other words, we want to predict when the tailing-off phase starts by monitoring the geometry of the current LP polytope via the condition number. We hoped to find a holistic metric to be used as proxy for determining when no more cuts should be added.
Unfortunately, we have not been able to determine any kind of such a relationship in our experiments. Even disabling most of the advanced tricks of an MILP solver to get a clearer picture did not help to provide a better understanding of condition numbers

Figure 6.7.: Unexpected developments of condition numbers (in log10 scale): Disabling cutting plane generation (sepaoff) leads to worse condition numbers. The left instance exhibits decreasing condition numbers going down the tree while for the right instance, the numbers are growing.
for this context.
Furthermore, identifying the actual tailing-off effect can be difficult for many practical instances. Often, jumps in the bound improvement suggest that the tailing-off has not yet begun. This makes it hard to label the corresponding condition numbers to train a machine learning algorithm or even just to compute a regression model.

For general purpose MILP instances we are not optimistic that we can provide meaningful algorithmic control of the solver to detect tailing-off based on condition numbers. The currently used methods in SCIP of discontinuing the cutting phase, for example when detecting stalling, appear to be sufficient if not superior because of the reduced computational requirements: Inspecting the bound and gap improvement is significantly less expensive than computing condition numbers.
After investigating many different experiments, Prof. Ted Ralphs compared our attempts to predict and learn a pattern from condition numbers during the MILP solving process with "doing a weather forecast for different planets", each planet resembling an individual problem instance.
In Figure 6.6 and Figure 6.7 we can see that the condition number trend in the
branch-and-cut tree can be very unexpected.

### 6.4. LP Condition Numbers for MILPs

The difficulty of defining a condition number for LPs mainly lies in the fact that there are so many different basis matrices that are encountered along the way and even neighboring bases may have significantly different condition numbers. We end up with even more possibilities when considering the additional degrees of freedom introduced by numerical tolerances.

In this section, we compute LP condition numbers $\kappa_{\text {LP }}$ as defined in Ordonez and Freund (2003) for a range of MILPs and compare those numbers to other metrics like the attention level. We want to investigate if this a priori measurement can be used to provide additional information about the expected numerical features of the instances during the optimization process.
We follow the proposed approach of Ordonez and Freund (2003) in computing the this condition number measure $\mathrm{K}_{\mathrm{LP}}(\mathrm{d})$

$$
\mathrm{K}_{\mathrm{LP}}(\mathrm{~d}):=\frac{\|\mathrm{d}\|}{\min \left\{\rho_{\mathrm{P}}(\mathrm{~d}), \rho_{\mathrm{D}}(\mathrm{~d})\right\}}
$$

for a general LP d with

$$
\begin{align*}
& \mathrm{d}:=\min c^{\top} x \\
& \text { s.t. } \quad A_{i .} x \leq b_{i} \text {, for } i \in L \text {, } \\
& A_{i .} x=b_{i} \text {, for } i \in E \text {, } \\
& A_{i .} x \geq b_{i} \text {, for } i \in G \text {, }  \tag{6.3}\\
& x_{j} \geq 0 \text { for } j \in L_{B} \text {, } \\
& x_{j} \leq 0 \text { for } j \in U_{B} .
\end{align*}
$$

The components $\rho_{\mathrm{P}}(\mathrm{d})$ and $\rho_{\mathrm{D}}(\mathrm{d})$ are calculated as

$$
\begin{align*}
& \rho_{P}(d)=\min _{\substack{i \in\{1, \ldots, \mathfrak{m}\} \\
j \in\{-1,1\}}} \min _{y, s^{+}, s^{-}, v} \max \left\{\left\|A^{\top} y+s^{+}-s^{-}\right\|_{1},\left|b^{\top} y-v\right|\right\} \\
& \text { s.t. } y_{i}=\mathfrak{j}, \\
& y_{l} \leq 0 \text { for } l \in L \\
& y_{l} \geq 0 \text { for } l \in G,  \tag{6.4}\\
& s_{k}^{-}=0 \text { for } k \in N \backslash U_{B}, \\
& s_{k}^{+}=0 \text { for } k \in N \backslash L_{B}, \\
& v+\sum_{k \in L_{B}} l_{k} s_{k}^{+}-\sum_{k \in U_{B}} u_{k} s_{k}^{-} \geq 0, \\
& s^{+}, s^{-} \geq 0
\end{align*}
$$

and

$$
\begin{align*}
& \rho_{\mathrm{D}}(\mathrm{~d})=\min _{\substack{i \in\{1, \ldots, n\} \\
j \in\{-1,1\}}} \min _{\substack{\text { in }, g}} \max \left\{\|A x-p\|_{1},\left|c^{\top} x+g\right|\right\} \\
& \text { s.t. } x_{i}=j, \\
& x_{k} \geq 0 \text { for } k \in L_{B}, \\
& x_{k} \leq 0 \text { for } k \in U_{B},  \tag{6.5}\\
& p_{l} \leq 0 \text { for } l \in L, \\
& p_{l}=0 \text { for } l \in E, \\
& p_{l} \geq 0 \text { for } l \in G, \\
& g \geq 0 .
\end{align*}
$$

As we can see from the definitions of $\rho_{P}$ and $\rho_{D}$, we need to solve $2 n+2 m$ LPs to compute these values: there are two LPs for every $j$ and every $i$, spanning the number of rows and the number of columns. Since there is only a minor change between the individual LPs, we can warm-start the solving process from the previous iteration.
Furthermore, we need to compute the scaling value $\|\mathrm{d}\|$ as:

$$
\|\mathrm{d}\|=\max \left\{\|A\|_{\infty, 1},\|\mathrm{~b}\|_{1},\|\mathrm{c}\|_{1}\right\} .
$$

Here, the vector norm for $b$ and $c$ is chosen as the 1 -norm $\|b\|_{1}:=\sum_{i=1}^{n}\left|b_{i}\right|$ while the matrix norm for $A$ is

$$
\|A\|_{\infty, 1}:=\max \left\{\|A x\|_{1} \text { with }\|x\|_{\infty}=1\right\} .
$$

To avoid the expensive computation of this norm, we follow the approach of Ordonez and Freund (2003) and employ lower and upper bounds instead as

$$
\max \left\{\|A\|_{1,1},\|A\|_{2,2},\|A\|_{F},\|A e\|_{1},\|A \tilde{a}\|_{1}\right\} \leq\|A\|_{\infty, 1} \leq \min \left\{\|A\|_{L_{1}}, \sqrt{n m}\|A\|_{2,2}\right\}
$$

where $e$ is the vector of ones and $\tilde{a}_{j}:=\operatorname{sign}\left(A_{i^{*}, j}\right)$ with $i^{*}:=\operatorname{argmax}_{i=1, \ldots, m}\left\|A_{i .}.\right\| 1_{1}$.
The amount of work to compute $\mathrm{K}_{\mathrm{LP}}$ for any given LP or MILP is significant and we cannot hope to use this approach in practice for reasonably sized problems.
Nevertheless, we hoped to predict or estimate the numerical difficulties solvers might encounter-as the plots of the collected data in Figure 6.8 show, there is no identifiable trend or correlation between the different metrics. We include runs with both CPLEX and XPRESS to provide more solver-agnostic results.

It appears there is no clear connection between (the logarithm of) this a priori computed stability measure $\mathrm{K}_{\mathrm{LP}}$ and those that can be extracted during or after the solving process. Neither the attention level, that is, the aggregation of all $k$ values, nor the maximal $\kappa$ itself relate to the $\kappa_{\text {LP }}$ value. We can also see that there is a fairly large number of instances with an infinite $\kappa_{L P}$ value, here represented by those values $\geq 10^{20}$ while the largest condition numbers in the tree are almost always smaller than $10^{15}$ and often a lot smaller. We can also spot this discrepancy in the comparison with the attention level that is also not signalling a numerically difficult model. This

Figure 6.8.: Statistics of the $\kappa_{\text {LP }}$ values and the tree condition numbers for various MILPs. Note that the $\kappa_{\text {Lp }}$ values are in each case the lower bounds from the estimation. The lower right subplot shows the $\mathrm{K}_{\mathrm{LP}}$ distribution which is independent of the solver.
once again demonstrates how hard it is to grasp and understand numerical issues that occur in MILP solvers. Table B. 4 lists all our collected Klp $^{\text {values as well as the }}$ largest encountered condition numbers in the tree and the attention level as defined in Equation (6.2).
The code to reproduce these computations is available on GitHub ${ }^{4}$, both as updated version of the original code from Ordonez and Freund (2003) using CPLEX and as Python version using Gurobi as LP solver.

### 6.5. Geometry of the Polyhedron and its Impact on Branching

The geometry of the polyhedron, that is, whether it is very thin in a few directions can make a difference in how many branch-and-bound nodes are necessary to find the optimal solution. Here, it can also be useful to know the thin directions and focus on the corresponding variable axis when deciding how to branch. This relation has been investigated by Derpich and Vera (2006) with somewhat promising results. By intuition it seems clear that one should incorporate the thinness of the polyhedron to avoid branching on directions that may generate a larger number of nodes. On the other hand, we also need to keep track of the remaining branching criteria so only a combined strategy can be successful.
Krishnamoorthy (2017) constructed counter examples to show that our intuition fails us when it comes to branching in thin directions and Mahajan and Ralphs (2010) proved that finding the best direction is an $\mathcal{N} \mathcal{P}$-hard problem itself.
What might be interesting to investigate is whether problems with a rather thin feasible region are more difficult to solve than those with a more uniform shape.

### 6.6. Exact MILP Solving

There have also been multiple attempts to mitigate the numerical issues of traditional solvers based on double precision arithmetic and implement exact rational MILP solvers, instead.
Typically, computers use a floating point representation for numbers. Computer codes can make use of different data types that determine the accuracy of this digital representation and a short comparison of some of those is given in Table 6.1.
A consequence of this limited binary representation of an uncountably infinite set of numbers is that there are numbers, for example $1 / 3$, that cannot be represented accurately. Instead, the digital number may deviate from the exact value up to the epsilon value of the chosen data type.
This is also why computations with the prevalent double data type are using a tolerance value of about $10^{-6}$ : As long as our condition numbers remain well below a value of $10^{10}$ we can expect accurate results of up to a relative error of $10^{-6}$. In other words, unavoidable double precision errors of magnitude $10^{-16}$ are amplified up to

[^26]| data type | number of bits | mantissa | exponent | epsilon |
| :--- | ---: | ---: | ---: | ---: |
| float | 32 | 23 | 8 | $2^{-23} \approx 1 \times 10^{-7}$ |
| double | 64 | 52 | 11 | $2^{-52} \approx 2 \times 10^{-16}$ |
| __float80 | 80 | 63 | 15 | $2^{-63} \approx 1 \times 10^{-19}$ |
| __float128 | 128 | 112 | 15 | $2^{-112} \approx 2 \times 10^{-34}$ |

Table 6.1.: Different accuracies of floating point representations and their respective number of bits in mantissa and exponent as defined in the IEEE standard 754.
$10^{-6}$ for computations that involve a condition number of $10^{10}$. That is the reason for the attention level classification of condition number ranges in Equation (6.2).

In addition to the floating point data types in Table 6.1, SoPLex has the ability to use rational arithmetic throughout the most important parts of the solver and can also make use of the much faster iterative refinement technique presented in Section 3.9. In combination with the rational extension of SCIP that was first developed by Cook et al. (2013) and then further improved and refined by Eifler and Gleixner (2021) very impressive speedups could be achieved. This makes exact rational MILP solving a viable alternative when faced with instances that cannot be solved to satisfactory results with conventional codes. Most commercial MILP solvers like GUROBI, or XPRESS have options to switch to a higher precision arithmetic mode, often called quad precision using the __float128 data type. They do not implement a rational arithmetic, though.

Unfortunately, the use of rational arithmetic comes with a significant computational overhead because most CPU chips are not optimized to perform these operations efficiently, in sharp contrast to their double precision counterparts. This makes it often impractical for real-world applications and a numerically careful and stable implementation remains unavoidable.

### 6.7. Outlook and Future Work

We want to stress the exploratory nature of the results of this chapter. We believe that the fascinating topic of numerics in LP and MILP solvers is far from covered and well-understood but our computational results and analysis provide another useful contribution to guide and inspire future research.

Currently, the best practice is to inspect conspicuous models individually and trying to understand how to treat or circumvent numerical issues. Firstly, the main question is whether the bounds, right-hand sides, and matrix and objective coefficients are all in some reasonable and confined range. Secondly, we can analyze more complicated features that for example take into account certain condition number measures. Still, careful modeling will remain key in avoiding numerically difficult instances yielding
questionable results.
From working with the large-scale supply network planning instances from our industry partner SAP (see Gamrath, Gleixner, et al., 2019), we realized a rather obscure numerical detail: The infinity value of SCIP (all larger values are treated as infinity) had to be increased from $10^{20}$ to $10^{30}$ to account for the huge solution values that otherwise triggered incorrect results. Furthermore, numerical tolerances frequently allowed small violations in the presolved space and got amplified in the original formulation, effectively rendering the solution to be infeasible. In those cases, expectations regarding the interpretability or correctness of the reported results need to be adjusted accordingly.
As mentioned earlier, also a very stable algorithm cannot prevent numerical issues stemming from a high condition number because of an unfavorable formulation. A solution that is applicable to all kinds of problems is not likely to be found without sacrificing a lot of performance by using exact arithmetic during the computations.
At the moment, the most promising direction is to implement reliable warning messages that alert users when a solution may not be fully trusted. Ideally, these warnings should be accompanied by hints and suggestions pointing to the root causes and how to avoid them in the future. Klotz (2014) provides an excellent practical guide about this topic. Machine learning techniques could be a suitable tool to help with these tasks as proposed by FICO XPRESs blog post mentioned before and by Berthold and Hendel (2021).
In addition, we need to keep looking for even more stable and numerically robust algorithms and implementations as well as to develop new measures to analyze our model instances and to enhance the prediction of their behavior during the solving process.

## Chapter 7

## Conclusion

Linear programming is the central theme of this dissertation-from simplex techniques to numerical experiments to LP-based visualizations of MILP solving.

In this thesis we presented various ways how LP solving influences and impacts the MILP solver SCIP. We gave an overview of the implementational details of the simplex solver SoPLex and explained how the MILP performance can be improved by treating the LP solver less like a black box.
With LP solution polishing in Chapter 5 , we demonstrated an efficient way to exploit degeneracy effects during the optimization of LP relaxations to return less fractional variable assignments in the computed solutions. Due to the abundance of degenerate LP relaxations in general MILPs, this technique could be applied frequently without introducing a detrimental overhead. The reduced fractionality of these polished LP solutions provided a decent performance benefit for SCIP. We also discussed how further insight from the additional simplex iterations might be useful for other components of an MILP solver.

In this regard, SCIP's restricting interface to the LP solver can be detrimental to similar algorithmic developments as it always requires a certain overhead and additional implementational effort. On the other hand, SCIP's modularity allowed for many of our investigations and experiments in the first place. Our experiments in Chapter 4 compared the performance of the available LP solvers in SCIP and how this can impact important metrics like the root gap and the node throughput.
We also learnt that persistent scaling is causing a significant positive performance impact-something quite unexpected but very welcome. The initial goal of implementing this advanced scaling feature was merely to improve the numerical stability and to reduce the number of rejected solutions containing too large violations. This also demonstrated that numerical features are important to consider when trying to improve the sheer performance of a solver.
Unfortunately, regardless of our best efforts to push the general MILP performance using some of the simplex additions and improvements presented in Chapter 3, like the bound flipping ratio test or sparsity exploitation techniques, we could only achieve a measurable effect on LP models or on selected MILP instances. In Chapter 4 we also

## 7. Conclusion

demonstrated the often unpredictable nature of MILP solving and how the LP solver influences the overall MILP performance of SCIP.

Going back to our initial conjecture of " $L P$ not mattering for MILP", we showed that it is not just about the speed of an LP solver but also, and maybe more importantly, how stable and reliable it is implemented and integrated into the MILP framework. Furthermore, our numerous experiments showed that the fraction of time spent in the LP solver is very similar across most solver implementations. This indicated that even a considerable performance difference between them did not carry over as pronounced to the MILP performance.

We are certain that the competitive landscape in the field of mathematical optimization is going to keep on changing and adapting to new technologies and new research advancements. We also tried to capture and honor this remarkable progress in our work presented in Appendix A.
We hope that our experiments concerning numerical features of LP and MILP solving shined a light on this topic and helped to gain a better understanding of the effects of branching and cutting. Despite the somewhat inconclusive results in Chapter 6, a very positive and successful outcome has been the TreeD project. TreeD provided interesting visualizations of MILP solving trees and can also conveniently be used as an analytics framework to collect various data during the solving process.
With Treed, we also demonstrated the practicality of PySCIPOPT and showed how new tools can be built and distributed on the provided framework and foundation that are presented in Chapter 2. The PYSCIPOPT project proved to be a reliable and welcome addition to the SCIP Optimization Suite and has since been used in numerous academic projects. This has been an important step in making the field of mathematical programming and optimization more accessible to a wider audience who may not be willing to dive into the technical details of SCIP.

Concerning the implications of the numerical experiments in Chapter 6, we are still confident that incorporating the condition number into algorithmic decisions in the MILP solver can be beneficial-we may just have to find the right questions to ask in this regard. We are expecting further developments in this field of interest and are convinced that our contributions can be useful to provide a better understanding of numerical features in MILP solvers.

## Appendix A

## Mittelmann Benchmark Plots

Prof. Hans Mittelmann (Arizona State University) maintains the largest publicly available benchmark data set for linear, mixed-integer, nonlinear, and combinatorial optimization problems ${ }^{1}$. His benchmarks are unique in the way that they allow comparisons between both commercial and open-source solvers and are usually kept up-todate with new versions of these solvers.
Solvers are compared on a set of instances for every class of problems, using a certain time limit. Runs that do not end in an optimal solution are counted as timeouts, without further penalization added. The number of correctly solved instances is also displayed.
The benchmarks themselves are performed without any stabilization techniques like different random seeds and some of the test sets are too small to provide a clear assertion of each solvers general performance.
Nevertheless, we are very happy that these benchmarks exist and are maintained with such passionate commitment. As the results are only available in plain text format and hence quite hard to process and analyze, we created an interactive web application called mittelmann-plots (Miltenberger, 2021a) that uses the Python graphing library Plotly ${ }^{2}$ to illustrate the individual results.

For every single class of benchmarks there is a table that automatically sorts the solvers by their respective scores and also displays the percentages of solved instances. The scores are computed by taking the shifted geometric mean of all solving times or time outs. The solver with the smallest mean is declared the winner and all scores are divided by the best score to achieve a relative comparison amongst all solvers. In addition to that, we include a "virtual best" or "portfolio" solver that assumes the best results for every single instance. This also depicts how much variability is present in the benchmarks and how much potential is still attainable by the individual solvers.
Such aggregated numbers can easily be misleading and it is always a good idea to also inspect the individual instance-wise performance results. Our tool provides an

[^27]interactive chart that displays both the absolute solving times for a selected solver as well as the relative speedup factors to all other solvers for every single instance as shown in Figure A.1. To account for huge differences in solving times ranging from fractions of a second to hours, we use a logarithmic scale for the relative numbers as well as the absolute solving times.
We believe that this visualization tool provides significantly added value to the raw benchmark results on Hans Mittelmann's webpage.

## Appendix B

## Experimental Data and Results

This appendix provides full data tables of the experiments conducted for the thesis and presented in the respective chapters.
We mark unsuccessful optimizations with an asterisk "*" at the respective times for that instance and setting. Additionally, we use an exclamation mark "!" to highlight infeasible instances and a " + " when a node limit has been reached.

## B. Experimental Data and Results
