Abstract. We describe an optimization process specially designed for regional hyperthermia of deep seated tumors in order to achieve desired steady–state temperature distributions. A nonlinear three–dimensional heat–transfer model based on temperature–dependent blood perfusion is applied to predict the temperature. Optimal heating is obtained by minimizing an integral object function which measures the distance between desired and model predicted temperatures. Sequential minima are calculated from successively improved constant–rate perfusion models employing a damped Newton method in an inner iteration. Numerical results for a Sigma 60 applicator are presented.

1 Introduction

Hyperthermia, i.e., heating tissue to 42 - 43°C, is a method of cancer therapy. It is normally applied as an additive therapy to enhance the effect of conventional radio- or chemotherapy. The standard way to produce local heating in the human body is the use of electromagnetic waves. We are mainly interested in regional hyperthermia of deep seated tumors. For this type of treatment usually a phased array of antennas surrounding the patient is used (see Fig. 1). The distribution of absorbed power within the patient’s body can be steered by selecting the amplitudes and phases of the antennas’ driving voltages. The space between the body and the antennas is filled by a so-called water bolus to avoid excessive heating of the skin.

From the viewpoint of computational medicine there are different challenges: 1. modelling and calculation of the electromagnetic field and the forced temperature, 2. optimization of the channel adjustments to achieve favourable interference patterns for a successful cancer therapy, 3. visualization of vector fields and temperature distributions on a very complicated geometry. All components have to be done for each individual patient within a medical planning system [1].

The purpose of our paper is to describe an optimization process based on a three–dimensional nonlinear heat transfer model. It is a rather difficult task to establish an appropriate physical model for the heat transport in the human body. Several
approaches can be found in the literature (see e.g. [14, 6]). The basis for our modelling is Pennes’ bio–heat–transfer equation which we equip with a temperature–dependent blood perfusion. A similar two–dimensional model was studied in [13] for ferromagnetic thermoseed hyperthermia.

To start the optimization process a specially designed object function is defined. Our aim is to get a temperature distribution which nearly avoids ”hot spots“ in healthy tissue and ”cold spots“ in the tumor region. In order to derive a fast optimization we approximate the nonlinear model by a sequence of linear ones which can be optimized very fast by applying a superposition principle.

Adaptive finite elements methods in space and linearly implicit integrators in time with step size control are used to solve the nonlinear bio–heat–transfer equation [7]. The implementation requires modern software design and programming languages as C or C++. Our code KARDOS is based on the programming environment KASKADE [3]. Additionally, a comfortable visualization tool is invaluable. We used the graphical system HYPERPLAN [1] for the presentation of our numerical results.

2 Nonlinear Heat Transfer Model

The basis model used in our simulation is the instationary bio–heat–transfer equation proposed by Pennes [10]

$$\rho c \frac{\partial T}{\partial t} = \text{div} (\kappa \text{grad} T) - c_b W (T - T_b) + Q_e,$$

(1)

where $\rho$ is the density of tissue, $c$ and $c_b$ are specific heat of tissue and blood, $\kappa$ is the thermal conductivity of tissue; $T_b$ is the blood temperature; $W$ is the mass flow rate of blood per unit volume of tissue. The power $Q_e$ deposited by an electric field $E$ in a tissue with electric conductivity $\sigma$ is given by

$$Q_e = \frac{1}{2} \sigma |E|^2.$$  

(2)

The total electric field $E$ can be computed by superposition of fields generated by different channels $E_j, j = 1, \ldots, N_{\text{chan}},$

$$E = \sum_{j=1}^{N_{\text{chan}}} a_j \exp(-i\theta_j) E_j,$$  

(3)

where the channel $j$ has amplitude $a_j$ and phase delay $\theta_j$. If complex values $z_j$ are defined as

$$z_j = a_j \exp(-i\theta_j)$$  

(4)

the absorbed power $Q_e$ can be expressed as a quadratic function of $z_j$
\[ Q_e = \frac{1}{2} \sigma \sum_{j,k=1}^{N_{chan}} z^*_j E_j^* E_k z_k . \]  

(5)

Besides the differential equation boundary conditions determine the temperature distribution. The heat exchange between body and water bolus can be described by the flux condition

\[ \kappa \frac{\partial T}{\partial n} = \beta (T_{bol} - T) \]  

(6)

where \( T_{bol} \) is the bolus temperature and \( \beta \) is the heat transfer coefficient. No heat loss is assumed in remaining regions. We use for our simulations \( \beta = 45 \text{W/m}^2/\text{°C} \) and \( T_{bol} = 25\text{°C} \).

Studies that predict temperatures in tissue models usually assume a constant-rate blood perfusion within each tissue. However, several experiments have shown that the response of vasculature in tissues to heat stress is strongly temperature-dependent [12]. When heated up to 41–43°C, temperatures that are commonly used in clinical hyperthermia, the blood flow in normal tissues, e.g., skin and muscle, increases significantly. In contrast, the tumor zone often appears to be so vulnerable to heat that the blood flow decreases upon heating.

We assume a temperature dependence of blood perfusion similar to [13]. For tumor tissue our curve has the same shape as the curve for tumor core used in [13], only the minimal and maximal perfusion differ. For muscle tissue we use a simplified curve consisting of a Gaussian profile describing the perfusion increase between 37°C and 45°C, and a plateau for temperatures above 45°C. In the raising part our curve differs only slightly from the one used in [13], the differences are small compared to the uncertainties of the underlying experimental data [12]. For temperatures above 45°C, in [13] a decrease of perfusion is assumed. This is motivated by the assumption that vasculature is destroyed if tissue is heated to such temperatures for about 30 minutes. Our optimization process guarantees that in the steady state the temperature in healthy tissue is always below this barrier. For fat tissue we also assume a temperature dependence of blood perfusion. We apply a curve with the same shape as for muscle tissue.

**Temperature-dependent blood perfusion in muscle:**

\[ W_{\text{muscle}} = \begin{cases} 
0.45 + 3.55 \exp \left( -\frac{(T - 45.0)^2}{12.0} \right), & T \leq 45.0 \\
4.00, & T > 45.0 
\end{cases} \]  

(7)

**Temperature-dependent blood perfusion in fat:**

\[ W_{\text{fat}} = \begin{cases} 
0.36 + 0.36 \exp \left( -\frac{(T - 45.0)^2}{12.0} \right), & T \leq 45.0 \\
0.72, & T > 45.0 
\end{cases} \]  

(8)
Temperature–dependent blood perfusion in tumor:

\[
W_{\text{tumor}} = \begin{cases} 
0.833, & T < 37.0 \\
0.833 - (T - 37.0)^{4.8}/5.438E+3, & 37.0 \leq T \leq 42.0 \\
0.416, & T > 42.0 
\end{cases}
\] (9)

The material properties of the involved tissues are summarized in Tab. 1. For blood we take \( T_b = 37^\circ C \), \( c_b = 3500 \text{W} \text{s}/\text{kg}/^\circ \text{C} \), and \( \rho_b = 1000 \text{kg}/\text{m}^3 \). If a constant–rate perfusion model is applied, we set \( W = 0.54 \text{kg}/\text{s}/\text{m}^3 \) for fat, \( W = 0.833 \text{kg}/\text{s}/\text{m}^3 \) for tumor, and \( W = 2.3 \text{kg}/\text{s}/\text{m}^3 \) for muscle.

Table 1: Material properties of tissues.

The stationary temperature field \( T \) can be computed as sum of the basal temperature \( T_{\text{bas}} \) determined by \( Q_e = 0 \), and the incremental temperature \( T_{\text{inc}} \) due to the hyperthermic application. We easily derive the stationary equations for \( T_{\text{bas}} \) and \( T_{\text{inc}} \)

\[
\text{div} (\kappa \text{grad} T_{\text{bas}}) - c_b W T_{\text{bas}} (T_{\text{bas}} - T_b) = 0, \]
\[
\kappa \frac{\partial T_{\text{bas}}}{\partial n} - \beta (T_{\text{out}} - T) = 0, \] (10)

and

\[
\text{div} (\kappa \text{grad} T_{\text{inc}}) - c_b (W T_{\text{inc}} + T_{\text{bas}}) T_{\text{inc}} + (W T_{\text{inc}} - W T_{\text{bas}}) (T_{\text{bas}} - T_b) + Q_e = 0, \]
\[
\kappa \frac{\partial T_{\text{inc}}}{\partial n} + \beta T_{\text{inc}} = 0. \] (11)

This splitting allows us to clearly distinguish between local effects forced by the permanent cooling of the human body at the surface and the heating by the electromagnetic field. Therefore, in an adaptive approach most of the refinement can be concentrated in regions where the power \( Q_e \) is large, e.g., in the tumor zone.
3 Grid Generation and Adaptive FEM

For patient specific treatment planning we create a tetrahedral model based on a set of CT-scans of the patient. Prior to grid generation, a segmentation of the CT data is performed, i.e., the relevant tissue compartments are defined on each scan.

![Patient model (torso) and hyperthermia applicator. The patient is surrounded by 8 antennas emitting radiowaves. A water-filled bolus is placed between patient and antennas.](image)

Our method for generating a patient model consists of three steps:
First we extract the compartment surfaces from the segmented CT data. For this purpose we have generalized the marching cubes algorithm [8], which is well-known in computer graphics, for non-binary classifications [5]. Our method creates a consistent description of the compartment interfaces. They are composed of so-called patches each separating two different compartments.
Second we perform a coarsening of the patches to get surfaces suitable for tetrahedron generation. We estimate the principal curvatures of the patches to be remeshed, and adapt the triangle size to surface curvature. For remeshing we use an advancing front method: Starting from the boundary of a patch we cover the whole patch with triangles.
Third we fill each tissue compartment with tetrahedra. Again we use an advancing front method. The compartment’s surface is composed from the correspond-
ing patches. At the beginning the advancing front is identical with this surface. Then repeatedly a triangle of the advancing front is selected and a fourth point is searched such that the resulting tetrahedron resembles an equilateral one as much as possible. This procedure is continued until the whole compartment is filled with tetrahedra [11].

The derived tetrahedral patient model is the basis for the formulation of a finite element method to approximate the bio–heat–transfer equation. We solve it adaptively both in time and space [7] in order to get efficiently more accurate solutions. In [4] simulations with coarse and adaptively improved grids indicated significant differences in the tissue temperatures. We discretize time first and approximate the momentary temperature by continuous piecewise linear functions. Refinement takes place in those regions where the estimated error is higher than a prescribed tolerance. A multilevel iterative solution of the arising linear systems provides optimal computational complexity.

4 Optimization Process

Our goal is to control the amplitudes $z_j$, $j = 1, \ldots, N_{chan}$, of the independent channels in order to achieve an effective hyperthermia therapy. A favourable temperature distribution is characterized as follows:

1. Within the tumor a therapeutic temperature level of $42 - 43^\circ C$ is reached.
2. No larger regions of healthy tissue are heated to above $42 - 43^\circ C$.
3. Temperature in healthy tissue does not exceed certain temperature limits depending on the tissue type.

Taking into account these requirements we define an object function for optimizing the temperature field

$$
q = \int_{x \in \text{tumor} \land T < T_{ther}} (T_{ther} - T)^2 \, dx + \int_{x \in \text{tumor} \land T > T_{health}} (T - T_{health})^2 \, dx + p \int_{x \notin \text{tumor} \land T > T_{lim}} (T - T_{lim})^2 \, dx , \quad (12)
$$

where we use a therapeutic level $T_{ther} = 43^\circ C$, and a temperature $T_{health} = 42^\circ C$ that should not be exceeded in healthy tissue. The limits $T_{lim}$ are chosen tissue-dependent: $T_{lim} = 42^\circ C$ for more sensible tissue compartments (bladder, intestine) and $T_{lim} = 44^\circ C$ otherwise. To ensure high penalization for temperatures exceeding the limits we set $p = 1000$.

The definition of the object function as an integral of squares guarantees that regions with large deviations from the attempted temperatures, i.e., ”hot spots“ in healthy tissue and ”cold spots“ in the tumor, contribute large amounts to the object function. A similar optimization strategy for a phased array hyperthermia system based on a simpler object function is described in [9].

Optimization of the temperature distribution means to choose the amplitudes $z$
of each channel in such a way that the resulting temperature field minimizes the object function \( q \).

Using our piecewise linear finite element solution \( T_h \) and applying an integration formula based only on the vertices \( x_i \) (mass lumping), we get an approximation of the object function

\[
q_h = \sum_{i \in M_{h1}} w_i \frac{1}{4} (T_{ther} - T_h(x_i))^2 + \sum_{i \in M_{h2}} w_i \frac{1}{4} (T_h(x_i) - T_{health})^2 + p \sum_{i \in M_{h3}} w_i \frac{1}{4} (T_h(x_i) - T_{lim})^2
\]

with

\[
M_{h1} = \{ i : x_i \in \text{tumor}, T_h(x_i) < T_{ther} \}, \quad M_{h2} = \{ i : x_i \not\in \text{tumor}, T_h(x_i) > T_{health} \}, \quad M_{h3} = \{ i : x_i \not\in \text{tumor}, T_h(x_i) > T_{lim} \},
\]

where \( w_i \) stands for the volume of all tetrahedra of which \( x_i \) is a vertex.

In a next step we derive formulas which allow us to compute quickly a new temperature field for changing amplitudes. Let us first consider the linear model with a constant-rate perfusion in each tissue. Then from (11) it can be directly seen that \( T_{inc} \) depends linearly on the distribution of absorbed power \( Q_e \). Hence, a superposition principle is valid:

\[
T_{inc}(\alpha_1 Q_e^1 + \alpha_2 Q_e^2) = \alpha_1 T_{inc}(Q_e^1) + \alpha_2 T_{inc}(Q_e^2). \quad (14)
\]

According to the representation (5) we get

\[
T_{inc}(Q_e) = \sum_{j,k=1}^{N_{chan}} z_j^* T_{inc}(E_j^* E_k) z_k, \quad (15)
\]

and finally for the whole stationary temperature distribution

\[
T(Z) = T_{bas} + \sum_{j,k=1}^{N_{chan}} z_j^* T_{inc}(E_j^* E_k) z_k, \quad (16)
\]

where \( Z \) is the vector of all \( z_j \). The incremental temperatures \( T_{inc}(E_j^* E_k) \) can be derived from \( N_{chan}^2 \) basic calculations combining two channels. Consequently, for an arbitrary set of parameters \( z_j \) the object function can be computed very fast. This is also true for the first and second derivatives of the finite element solution \( T_h \) with respect to the parameters \( z_j \).

In the nonlinear case, relation (14) is no longer valid. Nevertheless, we can fix the nonlinear perfusion terms due to a given intermediate state \( Z_n \) of all amplitudes. Then we utilize representation (15) as an approximation in a neighborhood of \( Z_n \) to perform the minimization process. Doing so we get a better \( Z_{n+1} \) for which we solve the nonlinear heat equation. The arising perfusion \( W(T(Z_{n+1})) \) is once
again fixed and the optimization is done. Improving successively the constant-rate model of the perfusion in such a way, we end up with a nearly optimal adjustment of the parameters $z_j$ for the nonlinear model.

Employing a damped Newton method for the optimization, the iteration can be described as follows:

Choose initial value $Z_0^{(0)}$

for $n = 0, 1, \ldots$

Calculate stationary temperature $T(Z_n^{(0)})$

Calculate $W_n := W(T(Z_n^{(0)}))$

Calculate $T_{\text{inc}}(E_j^* E_k), j, k = 1, \ldots, N_{\text{chan}}$, employing $W_n$

for $k = 0, 1, \ldots$

Calculate $D^i q_h := \left. \frac{D^i q_h}{dZ_i} \right|_{Z=Z_n^{(k)}}$, $i = 1, 2$

Calculate $\Delta Z := -(D^2 q_h)^{-1} D^1 q_h$

Find $a_0 \in \{1, \frac{1}{2}, \frac{1}{4}, \ldots\}$ such that

$q_h(Z_n^{(k)} + a_0 \Delta Z) < q_h(Z_n^{(k)}) + \frac{1}{2}a_0 D^1 q_h \Delta Z$

Define $Z_n^{(k+1)} := Z_n^{(k)} + a_0 \Delta Z$

Finished?

Define $Z_{n+1}^{(0)} := Z_n^{(k+1)}$

Finished?

The inner iteration is terminated if the object function has changed by less than 0.02 within 10 iterations. To control the outer iteration we always compute the new stationary temperature $T(Z_{n+1}^{(0)})$ and compare it with the old one. If the difference becomes small enough (less than $0.05^\circ C$), we stop the optimization process.

5 Numerical Results

We report some data concerning a concrete optimization process for an individual patient. The used applicator consists of eight radio frequency antennas grouped in four antenna pairs (Sigma 60 Applicator of the BSD 2000 Hyperthermia System). Each group can have its own amplitude and phase. So, our aim is to control four
different complex values \( z_j \).

Tab. 2: Data of optimization process.

Fig. 2: Optimization of the four complex amplitudes plotted in a quadrilateral for each outer iteration step (left); optimized temperature distribution (right).

Fig. 3: Temperature–volume histograms for muscle (left) and tumor tissue (right) showing the differences between constant–rate and temperature–dependent perfusion.

First, we calculate an initial optimized \( Z_0^{(0)} \) employing our constant–rate perfusion model. Then we proceed as described in Section 4. The optimization comes to an end after five outer iteration steps. The corresponding values of the object function \( q_h \) and the maximal temperature difference are shown in Tab. 2. In Fig. 2 the convergence history of the vector \( Z_h^{(0)} \) is presented. For each outer
iteration step all complex amplitudes $z_j$ are plotted as vertices of a quadrilateral. We observe that the use of the nonlinear heat transfer model leads to a more uniform adjustment of $|z_j|$ and to a slight reduction of the phase differences. The smaller value of the object function for the nonlinear model (see Tab. 2) results from a better tumor heating (Fig. 2, right), which is also reflected by the temperature–volume histogram for tumor tissue shown in Fig. 3. The histogram for muscle tissue reveals that assuming the nonlinear model a much larger amount of tissue is heated above 40°C.
